Abstract

This specification describes remote checksum offload for encapsulation, which is a mechanism that provides checksum offload of encapsulated packets using rudimentary offload capabilities found in most Network Interface Card (NIC) devices. The outer header checksum (e.g. that in UDP or GRE) is enabled in packets and, with some additional meta information, a receiver is able to deduce the checksum to be set for an inner encapsulated packet. Effectively this offloads the computation of the inner checksum. Enabling the outer checksum in encapsulation has the additional advantage that it covers more of the packet than the inner checksum including the encapsulation headers.

## **1 Introduction**

Checksum offload is a capability of NICs where the checksum calculation for a transport layer packet (TCP, UDP, etc.) is performed by a device on behalf of the host stack. Checksum offload is applicable to both transmit and receive, where on transmit the device writes the computed checksum into the packet, and on receive the device provides the computed checksum of the packet or an indication that specific transport checksums were validated. This feature saves CPU cycles in the host and has become ubiquitous in modern NICs.

A host may both source transport packets and encapsulate them for transit over an underlying network. In this case, checksum offload is

still desirable, but now must be done on an encapsulated packet.

Many

deployed NICs are only capable of providing checksum offload for simple TCP or UDP packets. Such NICs typically use protocol specific mechanisms where they must parse headers in order to perform

checksum

calculations. Updating these NICs to perform checksum offload for encapsulation requires new parsing logic which is likely infeasible or at cost prohibitive.

In this specification we describe an alternative that uses rudimentary NIC offload features to support offloading checksum calculation of encapsulated packets. In this design, the outer checksum is enabled on transmit, and meta information indicating the location of the checksum field being offloaded and its starting point

for computation are sent with a packet. On receipt, after the outer checksum is verified, the receiver sets the offloaded checksum field per the computed packet checksum and the meta data.

## **2 Checksum offload background**

In this section we provide some background into checksum offload operation.

### **2.1 The Internet checksum**

The Internet checksum [[RFC0791](#)] is used by several Internet protocols

including IP [[RFC1122](#)], TCP [[RFC0793](#)], UDP [[RFC0768](#)] and GRE [[RFC2784](#)]. Efficient checksum calculation is critical to good performance [[RFC1071](#)], and the mathematical properties are useful in incrementally updating checksums [[RFC1624](#)]. An early approach to implementing checksum offload in hardware is described in [[RFC1936](#)].

TCP and UDP checksums cover a pseudo header which is composed of the

source and destination addresses of the corresponding IP packet,

[Page

upper layer packet length, and protocol. The checksum pseudo header is defined in [[RFC0768](#)] and [[RFC0793](#)] for IPv4, and in [[RFC2460](#)] for IPv6.

## **2.2 Transmit checksum offload**

In transmit checksum offload, a host networking stack defers the calculation and setting of a transport checksum in the packet to the device. A device may provide checksum offload only for specific protocols, or may provide a generic interface. In either case, only one offloaded checksum per packet is typical.

When using transmit checksum offload, a host stack must initialize the checksum field in the packet. This is done by setting to zero (GRE) or to the bitwise not of the pseudo header (UDP or TCP). The device proceeds by computing the packet checksum from the start of the transport header through to the end of the packet. The bitwise not of the resulting value is written in the checksum field of the transport packet.

### **2.2.1 Generic transmit offload**

A device can provide a generic interface for transmit checksum offload. Checksum offload is enabled by setting two fields in the transmit descriptor for a packet: start offset and checksum offset. The start offset indicates the byte in the packet where the checksum calculation should start. The checksum offset indicates the offset in the packet where the checksum value is to be written.

The generic interface is protocol agnostic, however only supports one offloaded checksum per packet. It is conceivable that a NIC could provide offload for more checksums by defining more than one checksum start, checksum offset pair in the transmit descriptor.

### **2.2.2 Protocol specific transmit offload**

Some devices support transmit checksum offload for very specific protocols. For instance, many legacy devices can only perform checksum offload for UDP/IP and TCP/IP packets. These devices parse transmitted packets in order to determine the checksum start and checksum offset. They may also ignore the value in the checksum field by setting it to zero for checksum computation and computing the checksum of the pseudo header themselves.

Protocol specific transmit offload is limited to the protocols a device supports. To support checksum offload of an encapsulated packet, a device must be able to parse the encapsulation layer in order to locate the inner packet.

### **2.3 Receive checksum offload**

Upon receiving a packet, a device may perform a checksum calculation over the packet or part of the packet depending on the protocol. A result of this calculation is returned in the meta data of the receive descriptor for the packet. The host stack can apply the result in verifying checksums as it processes the packet. The intent is that the offload will obviate the need for the networking stack to perform its own checksum calculation over the packet.

There are two basic methods of receive checksum offload: CHECKSUM\_COMPLETE and CHECKSUM\_UNNECESSARY.

#### **2.3.1 CHECKSUM\_COMPLETE**

A device may calculate the checksum of a whole packet (layer 2 payload) and return the resultant value to the host stack. The host stack can subsequently use this value to validate checksums in the packet. As the packet is parsed through various layers, the calculated checksum is updated to correspond to each layer (subtract out checksum for preceding bytes for a given header).

CHECKSUM\_COMPLETE is protocol agnostic and does not require any protocol awareness in the device. It works for any encapsulation and supports an arbitrary number of checksums in the packet.

#### **2.3.2 CHECKSUM\_UNNECESSARY**

A device may explicitly validate a checksum in a packet and return a flag in the receive descriptor that a transport checksum has been verified (host performing checksum computation is unnecessary). Some devices may be capable of validating more than one checksum in the packet, in which case the device returns a count of the number verified. Typically, only a positive signal is returned, if the device was unable to validate a checksum it does not return any information and the host will generally perform its own checksum computation. If a device returns a count of validations, this must refer to consecutive checksums that are present and validated in a packet (checksums cannot be skipped).

CHECKSUM\_UNNECESSARY is protocol specific, for instance in the case of UDP or TCP a device needs to consider the pseudo header in checksum validation. To support checksum offload of an encapsulated packet, a device must be able to parse the encapsulation layer in order to locate the inner packet.

### **3 Remote checksum offload**

Herbert

[Page

This section describes the remote checksum offload mechanism. This is primarily useful with UDP based encapsulation where the UDP checksum is enabled (not set to zero on transmit). The same technique could be applied to GRE encapsulation where the GRE checksum is enabled.

**3.1 Meta data format**

Remote checksum offload requires the sending of meta data with an encapsulated packet. This data is a pair of checksum start and checksum offset values. More than one offloaded checksum could be supported if multiple pairs are sent.

The meta data format for remote checksum offload is:

o Checksum start: starting offset for checksum computation relative to the start of the encapsulation header. This is typically the offset of a transport header (e.g. UDP or TCP).

o Checksum offset: Offset relative to the start of the encapsulation header where the derived checksum value is to be written. This typically is the offset of the checksum field in the transport header (e.g. UDP or TCP).

Support for remote checksum offload with specific encapsulation protocols is outside the scope of this document, however any encapsulation format that supports some reasonable form of optional meta data should be amenable. In Generic UDP Encapsulation [[GUE](#)] this would entail defining an optional field, in Geneve [[GENEVE](#)] a TLV would be defined, for NSH [[NSH](#)] the meta data can either be in a service header or within a TLV. In any scenario, what the offsets in the meta data are relative to must be unambiguous (for instance when used in NSH the offsets may be relative to the NSH header itself).

**3.2 Transmit operation**

The typical actions to set remote checksum offload on transmit are:

- 1) Transport layer creates a packet and indicates in internal packet meta data that checksum is to be offloaded to the NIC (normal transport layer processing for checksum offload). The checksum field is populated with the bitwise not of the checksum of the pseudo header or zero as appropriate.

Herbert  
6]

Expires February 2015

[Page

2) Encapsulation layer adds its headers to the packet including the offload meta data. The start offset and checksum offset are set accordingly.

3) Encapsulation layer arranges for checksum offload of the outer header checksum (e.g. UDP).

4) Packet is sent to the NIC. The NIC will perform transmit checksum offload and set the checksum field in the outer header. The inner header and rest of the packet are transmitted without modification.

### **3.3 Receiver operation**

The typical actions a host receiver does to support remote checksum offload are:

1) Receive packet and validate outer checksum following normal processing (e.g. validate non-zero UDP checksum).

2) Deduce full checksum for the IP packet. This is directly provided if device returns the packet checksum in CHECKSUM\_COMPLETE. If the device returned CHECKSUM\_UNNECESSARY, then the complete checksum can be trivially derived as either zero (GRE) or the bitwise not of the outer pseudo header (UDP).

3) From the packet checksum, subtract the checksum computed from the start of the packet (outer IP header) to the offset in the packet indicted by checksum start in the meta data. The result is the deduced checksum to set in the checksum field of the encapsulated transport packet.

In pseudo code:

```
csum: initialized to checksum computed from start (outer IP
header) to
    the end of the packet
start_of_packet: address of start of packet
offset_of_encap_hdr: relative to start_of_packet
csum_start: value from meta data
checksum(start, len): function to compute checksum from start
address
    for len bytes
```

```
csum -= checksum(start_of_packet, offset_of_encap_hdr +
csum_start)
```

4) Write the resultant checksum value into the packet at the offset provided by checksum offset in the meta data.

In pseudo code:

Herbert  
7]

Expires February 2015

[Page

csum\_offset: offset of checksum field

\*(start\_of\_packet + offset\_of\_encap\_hdr + csum\_offset) = csum

5) Checksum is verified at the transport layer using normal processing. This should not require any checksum computation over the packet since the complete checksum has already been provided.

### **3.4 Interaction with TCP segmentation offload**

Remote checksum offload may be useful with TCP Segmentation Offload (TSO) in order to avoid host checksum calculations at the receiver. This can be implemented on a transmitter as follows:

1) Host stack prepares a large segment for transmission including adding of encapsulation headers and the remote checksum option which refers to the encapsulated transport checksum in the large segment.

2) TSO is performed by the device taking encapsulation into account. The outer checksum is computed and written for each packet. The inner checksum is not computed, and the encapsulation header (including checksum meta data) is replicated for each packet.

3) At the receiver remote checksum offload processing occurs as normal for each packet.

## **4 Security Considerations**

Remote checksum offload should not impact protocol security.

## **5 IANA Considerations**

There are no IANA considerations in this specification. The remote checksum offload meta data may require an option number or type in specific encapsulation formats that support it.
