**The DNS-Based Authentication of Named Entities (DANE) Protocol for
Transport Layer Security (TLS)
draft-ietf-dane-protocol-18**

Abstract

Encrypted communication on the Internet often uses Transport Level Security (TLS), which depends on third parties to certify the keys used. This document improves on that situation by enabling the administrator of a domain name to certify the keys used in that domain's TLS servers. This requires matching improvements in TLS client software, but no change in TLS server software.

Status of this Memo

This Internet-Draft is submitted in full conformance with the provisions of [BCP 78](#) and [BCP 79](#).

Internet-Drafts are working documents of the Internet Engineering Task Force (IETF). Note that other groups may also distribute working documents as Internet-Drafts. The list of current Internet-Drafts is at <http://datatracker.ietf.org/drafts/current/>.

Internet-Drafts are draft documents valid for a maximum of six months and may be updated, replaced, or obsoleted by other documents at any time. It is inappropriate to use Internet-Drafts as reference material or to cite them other than as "work in progress."

This Internet-Draft will expire on September 10, 2012.

1. Introduction

1.1. Background of the Problem

Applications that communicate over the Internet often need to prevent eavesdropping, tampering, or forgery of their communications. The Transport Layer Security (TLS) protocol provides this kind of communications privacy over the Internet, using encryption.

The security properties of encryption systems depend strongly on the keys that they use. If secret keys are revealed, or if published keys can be replaced by bogus keys, these systems provide little or no security.

TLS uses certificates to bind keys and names. A certificate combines a published key with other information such as the name of the service that the key is used by, and this combination is digitally signed by another key. Having a certificate for a key is only helpful if you trust the other key that signed the certificate. If that other key was itself revealed or substituted, then its signature is worthless in proving anything about the first key.

On the Internet, this problem has been solved for years by entities called "Certification Authorities" (CAs). CAs protect their secret key vigorously, while supplying their public key to the software vendors who build TLS clients. They then sign certificates, and supply those to TLS servers. TLS client software uses a set of these CA keys as "trust anchors" to validate the signatures on certificates that the client receives from TLS servers. Client software typically allows any CA to usefully sign any other certificate.

This solution has gradually broken down because some CAs have become untrustworthy. A single trusted CA that betrays its trust, either voluntarily or by providing less-than-vigorous protection for its secrets and capabilities, can compromise any other certificate that TLS uses by signing a replacement certificate that contains a bogus key. Several real-world occurrences that have exploited such CAs for subversion of major web sites (presumably to abet wiretapping and large-scale fraud) have brought TLS's CA model into disrepute.

The DNS Security Extensions (DNSSEC) provides a similar model that involves trusted keys signing the information for untrusted keys. However, DNSSEC provides three significant improvements. Keys are tied to names in the Domain Name System (DNS), rather than to arbitrary identifying strings; this is more convenient for Internet protocols. Signed keys for any domain are accessible online through a straightforward query using the standard DNSSEC protocol, so there is no problem distributing the signed keys. Most significantly, the

keys associated with a domain name can only be signed by a key associated with the parent of that domain name; for example, the keys for "example.com" can only be signed by the keys for "com", and the keys for "com" can only be signed by the DNS root. This prevents an untrustworthy signer from compromising anyone's keys except those in their own subdomains. Like TLS, DNSSEC relies on public keys that come built into the DNSSEC client software, but these keys come only from a single root domain rather than from a multiplicity of CAs.

1.2. Securing the Association with a Server's Certificate

A TLS client begins a connection by exchanging messages with a TLS server. It looks up the server's name using the DNS to get Internet Protocol (IP) address associated with the name. It then begins a connection to a client-chosen port at that address, and sends an initial message there. However, the client does not yet know whether an adversary is intercepting and/or altering its communication before it reaches the TLS server. It does not even know whether the real TLS server associated with that domain name has ever received its initial messages.

The first response from the server in TLS may contain a certificate. In order for the TLS client to authenticate that it is talking to the expected TLS server, the client must validate that this certificate is associated with the domain name used by the client to get to the server. Currently, the client must extract the domain name from the certificate and must successfully validate the certificate, including chaining to a trust anchor.

There is a different way to authenticate the association of the server's certificate with the intended domain name without trusting an external CA. Given that the DNS administrator for a domain name is authorized to give identifying information about the zone, it makes sense to allow that administrator to also make an authoritative binding between the domain name and a certificate that might be used by a host at that domain name. The easiest way to do this is to use the DNS, securing the binding with DNSSEC.

There are many use cases for such functionality. [\[RFC6394\]](#) lists the ones that the DNS RRtype in this document are meant to apply. [\[RFC6394\]](#) also lists many requirements, most of which this document is believed to meet. [Section 5](#) covers the applicability of this document to the use cases in detail.

This document applies to both TLS [\[RFC5246\]](#) and DTLS [\[RFC6347\]](#). In order to make the document more readable, it mostly only talks about "TLS", but in all cases, it means "TLS or DTLS". This document only relates to securely associating certificates for TLS and DTLS with

host names; other security protocols and other forms of identification of TLS servers (such as IP addresses) are handled in other documents. For example, keys for IPsec are covered in [\[RFC4025\]](#) and keys for SSH are covered in [\[RFC4255\]](#).

1.3. Method For Securing Certificate Associations

A certificate association is formed from a piece of information identifying a certificate (such as the contents of the certificate or a trust anchor to which the certificate chains) and the domain name where the data is found. This document only applies to PKIX [\[RFC5280\]](#) certificates, not certificates of other formats.

A DNS query can return multiple certificate associations, such as in the case of different server software on a single host using different certificates, or in the case that a server is changing from one certificate to another.

This document defines a secure method to associate the certificate that is obtained from the TLS server with a domain name using DNS; the DNS information needs to be protected by DNSSEC. Because the certificate association was retrieved based on a DNS query, the domain name in the query is by definition associated with the certificate.

DNSSEC, which is defined in RFCs 4033, 4034, and 4035 ([\[RFC4033\]](#), [\[RFC4034\]](#), and [\[RFC4035\]](#)), uses cryptographic keys and digital signatures to provide authentication of DNS data. Information that is retrieved from the DNS and that is validated using DNSSEC is thereby proved to be the authoritative data. The DNSSEC signature MUST be validated on all responses that use DNSSEC in order to assure the proof of origin of the data. This document does not specify how DNSSEC validation occurs because there are many different proposals for how a client might get validated DNSSEC results.

This document only relates to securely getting the DNS information for the certificate association using DNSSEC; other secure DNS mechanisms are out of scope.

1.4. Terminology

The key words "MUST", "MUST NOT", "REQUIRED", "SHALL", "SHALL NOT", "SHOULD", "SHOULD NOT", "RECOMMENDED", "MAY", and "OPTIONAL" in this document are to be interpreted as described in [RFC 2119](#) [\[RFC2119\]](#).

This document also makes use of standard PKIX, DNSSEC, and TLS terminology. See [\[RFC5280\]](#), [\[RFC4033\]](#), and [\[RFC5246\]](#) respectively, for these terms. In addition, terms related to TLS-protected

application services and DNS names are taken from [\[RFC6125\]](#).

2. The TLSA Resource Record

The TLSA DNS resource record (RR) is used to associate a certificate with the domain name where the record is found. The semantics of how the TLSA RR is interpreted are given later in this document.

The type value for the TLSA RR type is TBD.

The TLSA RR is class independent.

The TLSA RR has no special TTL requirements.

2.1. TLSA RDATA Wire Format

The RDATA for a TLSA RR consists of a one octet usage type field, a one octet selector field, a one octet matching type field and the certificate association data field.

```

          1 1 1 1 1 1 1 1 1 1 2 2 2 2 2 2 2 2 2 2 3 3
0 1 2 3 4 5 6 7 8 9 0 1 2 3 4 5 6 7 8 9 0 1 2 3 4 5 6 7 8 9 0 1
+---+---+---+---+---+---+---+---+---+---+---+---+---+---+---+---+
|   Usage   | Selector | Matching Type |                               /
+---+---+---+---+---+---+---+---+---+---+---+---+---+---+---+---+
/                                                                 /
/               Certificate Association Data                       /
/                                                                 /
+---+---+---+---+---+---+---+---+---+---+---+---+---+---+---+---+

```

2.1.1. The Certificate Usage Field

A one-octet value, called "certificate usage" or just "usage", specifying the provided association that will be used to match the target certificate from the TLS handshake. This value is defined in a new IANA registry (see [Section 7.2](#)) in order to make it easier to add additional certificate usages in the future. The usages defined in this document are:

0 -- Certificate usage 0 is used to specify a CA certificate, or the public key of such a certificate, that must be found in any of the PKIX certification paths for the end entity certificate given by the server in TLS. This usage is sometimes referred to as "CA constraint" because it limits which CA can be used to issue certificates for a given service on a host. The target certificate MUST pass PKIX certification path validation and a CA certificate that matches the TLSA record MUST be included as part

of a valid certification path.

1 -- Certificate usage 1 is used to specify an end entity certificate, or the public key of such a certificate, that must be matched with the end entity certificate given by the server in TLS. This usage is sometimes referred to as "service certificate constraint" because it limits which end entity certificate may be used by a given service on a host. The target certificate MUST pass PKIX certification path validation and MUST match the TLSA record.

2 -- Certificate usage 2 is used to specify a certificate, or the public key of such a certificate, that must be used as the trust anchor when validating the end entity certificate given by the server in TLS. This usage is sometimes referred to as "trust anchor assertion" and allows a domain name administrator to specify a new trust anchor, for example if the domain issues its own certificates under its own CA that is not expected to be in the end users' collection of trust anchors. The target certificate MUST pass PKIX certification path validation, with any certificate matching the TLSA record considered to be a trust anchor for this certification path validation.

3 -- Certificate usage 3 is used to specify a certificate, or the public key of such a certificate, that must match the end entity certificate given by the server in TLS. This usage is sometimes referred to as "domain-issued certificate" because it allows for a domain name administrator to issue certificates for a domain without involving a third-party CA. The target certificate MUST match the TLSA record. The difference between certificate usage 1 and certificate usage 3 is that certificate usage 1 requires that the certificate pass PKIX validation, but PKIX validation is not tested for certificate usage 3.

The certificate usages defined in this document explicitly only apply to PKIX-formatted certificates in DER encoding. If TLS allows other formats later, or if extensions to this RRtype are made that accept other formats for certificates, those certificates will need their own certificate usage values.

2.1.2. The Selector Field

A one-octet value, called "selector", specifying which part of the TLS certificate presented by the server will be matched against the association data. This value is defined in a new IANA registry (see [Section 7.3](#)). The selectors defined in this document are:

- 0 -- Full certificate
- 1 -- SubjectPublicKeyInfo

2.1.3. The Matching Type Field

A one-octet value, called "matching type", specifying how the certificate association is presented. This value is defined in a new IANA registry (see [Section 7.4](#)). The types defined in this document are:

- 0 -- Exact match on selected content
- 1 -- SHA-256 hash of selected content [[RFC6234](#)]
- 2 -- SHA-512 hash of selected content [[RFC6234](#)]

If the TLSA record's matching type is a hash, the record SHOULD use the same hash algorithm that was used in the signature in the certificate. This will assist clients that support a small number of hash algorithms.

2.1.4. The Certificate Association Data Field

The "certificate association data" to be matched. This field contains the data to be matched. These bytes are either raw data (that is, the full certificate or its SubjectPublicKeyInfo, depending on the selector) for matching type 0, or the hash of the raw data for matching types 1 and 2. The data refers to the certificate in the association, not to the TLS ASN.1 Certificate object.

2.2. TLSA RR Presentation Format

The presentation format of the RDATA portion is as follows:

- o The certificate usage field MUST be represented as an unsigned decimal integer.
- o The selector field MUST be represented as an unsigned decimal integer.
- o The matching type field MUST be represented as an unsigned decimal integer.
- o The certificate association data field MUST be represented as a string of hexadecimal characters. Whitespace is allowed within the string of hexadecimal characters.

2.3. TLSA RR Examples

An example of a hashed (SHA-256) association of a PKIX CA certificate:

```
_443._tcp.www.example.com. IN TLSA (  
  0 0 1 d2abde240d7cd3ee6b4b28c54df034b9  
    7983a1d16e8a410e4561cb106618e971 )
```

An example of a hashed (SHA-512) subject public key association of a PKIX end entity certificate:

```
_443._tcp.www.example.com. IN TLSA (  
  1 1 2 92003ba34942dc74152e2f2c408d29ec  
    a5a520e7f2e06bb944f4dca346baf63c  
    1b177615d466f6c4b71c216a50292bd5  
    8c9ebdd2f74e38fe51ffd48c43326cbc )
```

An example of a full certificate association of a PKIX end entity certificate:

```
_443._tcp.www.example.com. IN TLSA (  
  3 0 0 30820307308201efa003020102020... )
```

3. Domain Names for TLS Certificate Associations

Unless there is a protocol-specific specification that is different than this one, TLSA resource records are stored at a prefixed DNS domain name. The prefix is prepared in the following manner:

1. The decimal representation of the port number on which a TLS-based service is assumed to exist is prepended with an underscore character ("_") to become the left-most label in the prepared domain name. This number has no leading zeros.
2. The protocol name of the transport on which a TLS-based service is assumed to exist is prepended with an underscore character ("_") to become the second left-most label in the prepared domain name. The transport names defined for this protocol are "tcp", "udp" and "sctp".
3. The domain name is appended to the result of step 2 to complete the prepared domain name.

For example, to request a TLSA resource record for an HTTP server running TLS on port 443 at "www.example.com", you would use "_443._tcp.www.example.com" in the request. To request a TLSA

resource record for an SMTP server running the STARTTLS protocol on port 25 at "mail.example.com", you would use "_25._tcp.mail.example.com".

4. Use of TLSA Records in TLS

[Section 2.1](#) of this document defines the mandatory matching rules for the data from the TLSA certificate associations and the certificates received from the TLS server.

The TLS session that is to be set up MUST be for the specific port number and transport name that was given in the TLSA query.

Some specifications for applications that run under TLS, such as [\[RFC2818\]](#) for HTTP, require the server's certificate to have a domain name that matches the host name expected by the client. Some specifications such as [\[RFC6125\]](#) detail how to match the identity given in a PKIX certificate with those expected by the user.

An implementation of this protocol makes a DNS query for TLSA records, validates these records using DNSSEC, and uses the resulting TLSA records and validation status to modify its responses to the TLS server.

If a host is using TLSA usage type 2 for its certificate, the corresponding TLS server SHOULD send the certificate that is referenced just like it currently sends intermediate certificates.

Determining whether a TLSA RRset can be used depends on the DNSSEC validation state (as defined in [\[RFC4033\]](#)).

- o A TLSA RRset whose DNSSEC validation state is secure MUST be used as a certificate association for TLS unless a local policy would prohibit the use of the specific certificate association in the secure TLSA RRset.
- o If the DNSSEC validation state on the response to the request for the TLSA RRset is bogus, this MUST cause TLS not to be started or, if the TLS negotiation is already in progress, MUST cause the connection to be aborted.
- o A TLSA RRset whose DNSSEC validation state is indeterminate or insecure cannot be used for TLS and MUST be considered unusable.

Clients which validate the DNSSEC signatures themselves MUST use standard DNSSEC validation procedures. Clients that rely on another entity to perform the DNSSEC signature validation MUST use a secure

mechanism between themselves and the validator. Examples of secure transports to other hosts include TSIG [[RFC2845](#)], SIG(0) [[RFC2931](#)], and IPsec [[RFC6071](#)]. Note that it is not sufficient to use secure transport to a DNS resolver that does not do DNSSEC signature validation.

If a certificate association contains a certificate usage, selector, or matching type that is not understood by the TLS client, that certificate association MUST be considered unusable. If the comparison data for a certificate is malformed, the certificate association MUST be considered unusable.

If a certificate association contains a matching type or certificate association data that uses a cryptographic algorithm that is considered too weak for the TLS client's policy, the certificate association MUST be marked as unusable.

If an application receives zero usable certificate associations, it processes TLS in the normal fashion without any input from the TLSA records. If an application receives one or more usable certificate associations, it attempts to match each certificate association with the TLS server's end entity certificate until a successful match is found.

5. TLSA and DANE Use Cases and Requirements

The different types of certificate associations defined in TLSA are matched with various sections of [[RFC6394](#)]. The use cases from [Section 3 of \[RFC6394\]](#) are covered in this document as follows:

3.1 CA Constraints -- Implemented using certificate usage 0.

3.2 Certificate Constraints -- Implemented using certificate usage 1.

3.3 Trust Anchor Assertion and Domain-Issued Certificates -- Implemented using certificate usages 2 and 3, respectively.

The requirements from [Section 4 of \[RFC6394\]](#) are covered in this document as follows:

Multiple Ports -- The TLSA records for different application services running on a single host can be distinguished through the service name and port number prefixed to the host name (see [Section 3](#)).

No Downgrade -- [Section 4](#) specifies the conditions under which a client can process and act upon TLSA records. Specifically, if the DNSSEC status for the TLSA resource record set is determined to be bogus, the TLS connection (if started) will fail.

Encapsulation -- Covered in the TLSA response semantics.

Predictability -- The appendixes of this specification provide operational considerations and implementation guidance in order to enable application developers to form a consistent interpretation of the recommended DANE client behavior.

Opportunistic Security -- If a client conformant to this specification can reliably determine the presence of a TLSA record, it will attempt to use this information. Conversely, if a client can reliably determine the absence of any TLSA record, it will fall back to processing TLS in the normal fashion. This is discussed in [Section 4](#).

Combination -- Multiple TLSA records can be published for a given host name, thus enabling the client to construct multiple TLSA certificate associations that reflect different DANE assertions. No support is provided to combine two TLSA certificate associations in a single operation.

Roll-over -- TLSA records are processed in the normal manner within the scope of DNS protocol, including the TTL expiration of the records. This ensures that clients will not latch onto assertions made by expired TLSA records, and will be able to transition from using one DANE public key or certificate usage type to another.

Simple Key Management -- The SubjectPublicKeyInfo selector in the TLSA record provides a mode that enables a domain holder to only have to maintain a single long-lived public/private key pair without the need to manage certificates. [Appendix A](#) outlines the usefulness and the potential downsides to using this mode.

Minimal Dependencies -- This specification relies on DNSSEC to protect the origin authenticity and integrity of the TLSA resource record set. Additionally, if DNSSEC validation is not performed on the system that wishes to use TLSA certificate bindings, this specification requires that the "last mile" be over a secure transport. There are no other deployment dependencies for this approach.

Minimal Options -- The operating modes map precisely to the DANE use cases and requirements. DNSSEC use is mandatory in that this specification encourages applications to use TLSA records that are only shown to be validated.

Wild Cards -- Covered in a limited manner in the TLSA request syntax; see [Appendix A](#).

Redirection -- Covered in the TLSA request syntax; see [Appendix A](#).

6. Mandatory-to-Implement Features

TLS clients conforming to this specification MUST be able to correctly interpret TLSA records with certificate usages 0, 1, 2, and 3. TLS clients conforming to this specification MUST be able to compare a certificate association with a certificate from the TLS handshake using selectors type 0 and 1, and matching type 0 (no hash used) and matching type 1 (SHA-256), and SHOULD be able to make such comparisons with matching type 2 (SHA-512).

At the time this is written, it is expected that there will be a new family of hash algorithms called SHA-3 within the next few years. It is expected that some of the SHA-3 algorithms will be mandatory and/or recommended for TLSA records after the algorithms are fully defined. At that time, this specification will be updated.

7. IANA Considerations

In the following sections, "RFC Required" was chosen for TLSA usages and "Specification Required" for selectors and matching types because of the amount of detail that is likely to be needed for implementers to correctly implement new usages as compared to new selectors and matching types.

7.1. TLSA RRtype

This document uses a new DNS RR type, TLSA, whose value is TBD. A separate request for the RR type will be submitted to the expert reviewer, and future versions of this document will have that value instead of TBD.

7.2. TLSA Usages

This document creates a new registry, "Certificate Usages for TLSA Resource Records". The registry policy is "RFC Required". The initial entries in the registry are:

Value	Short description	Reference

0	CA constraint	[This]
1	Service certificate constraint	[This]
2	Trust anchor assertion	[This]
3	Domain-issued certificate	[This]
4-254	Unassigned	
255	Private use	

Applications to the registry can request specific values that have yet to be assigned.

[7.3.](#) TLSA Selectors

This document creates a new registry, "Selectors for TLSA Resource Records". The registry policy is "Specification Required". The initial entries in the registry are:

Value	Short description	Reference

0	Full Certificate	[This]
1	SubjectPublicKeyInfo	[This]
2-254	Unassigned	
255	Private use	

Applications to the registry can request specific values that have yet to be assigned.

[7.4.](#) TLSA Matching Types

This document creates a new registry, "Matching Types for TLSA Resource Records". The registry policy is "Specification Required". The initial entries in the registry are:

Value	Short description	Reference

0	No hash used	[This]
1	SHA-256	RFC 6234
2	SHA-512	RFC 6234
3-254	Unassigned	
255	Private use	

Applications to the registry can request specific values that have yet to be assigned.

8. Security Considerations

The security of the DNS RRtype described in this document relies on the security of DNSSEC as used by the client requesting A/AAAA and TLSA records.

A DNS administrator who goes rogue and changes both the A/AAAA and TLSA records for a domain name can cause the user to go to an unauthorized server that will appear authorized, unless the client performs PKIX certification path validation and rejects the certificate. That administrator could probably get a certificate issued anyway, so this is not an additional threat.

If the authentication mechanism for adding or changing TLSA data in a zone is weaker than the authentication mechanism for changing the A/AAAA records, a man-in-the-middle who can redirect traffic to their site may be able to impersonate the attacked host in TLS if they can use the weaker authentication mechanism. A better design for authenticating DNS would be to have the same level of authentication used for all DNS additions and changes for a particular domain name.

SSL proxies can sometimes act as a man-in-the-middle for TLS clients. In these scenarios, the clients add a new trust anchor whose private key is kept on the SSL proxy; the proxy intercepts TLS requests, creates a new TLS session with the intended host, and sets up a TLS session with the client using a certificate that chains to the trust anchor installed in the client by the proxy. In such environments, using TLSA records will prevent the SSL proxy from functioning as expected because the TLS client will get a certificate association from the DNS that will not match the certificate that the SSL proxy uses with the client. The client, seeing the proxy's new certificate for the supposed destination will not set up a TLS session.

Client treatment of any information included in the certificate trust anchor is a matter of local policy. This specification does not mandate that such information be inspected or validated by the server's domain name administrator.

If a server's certificate is revoked, or if an intermediate CA in a chain between the end entity and a trust anchor has its certificate revoked, a TLSA record with a certificate type of 2 that matches the revoked certificate would in essence override the revocation because the client would treat that revoked certificate as a trust anchor and thus not check its revocation status. Because of this, domain administrators need to be responsible for being sure that the key or certificate used in TLSA records with a certificate type of 2 are in fact able to be used as reliable trust anchors.

Certificates that are delivered in TLSA with usage type 2 fundamentally change the way the TLS server's end entity certificate is evaluated. For example, the server's certificate might chain to an existing CA through an intermediate CA that has certain policy restrictions, and the certificate would not pass those restrictions and thus normally be rejected. That intermediate CA could issue itself a new certificate without the policy restrictions and tell its customers to use that certificate with usage type 2. This in essence allows an intermediate CA to become a trust anchor for certificates that the end user might have expected to chain to an existing trust anchor.

If an administrator wishes to stop using a TLSA record, the administrator can simply remove it from the DNS. Normal clients will stop using the TLSA record after the TTL has expired. Replay attacks against the TLSA record are not possible after the expiration date on the RRSig of the TLSA record that was removed.

The client's full trust of a certificate retrieved from a TLSA record with a certificate usage type of 2 or 3 may be a matter of local policy. While such trust is limited to the specific domain name for which the TLSA query was made, local policy may deny the trust or further restrict the conditions under which that trust is permitted.

8.1. DNS Caching

Implementations of this protocol rely heavily on the DNS, and are thus prone to security attacks based on the deliberate mis-association of TLSA records and DNS names. Implementations need to be cautious in assuming the continuing validity of an association between a TLSA record and a DNS name.

In particular, implementations SHOULD rely on their DNS resolver for confirmation of an association between a TLSA record and a DNS name, rather than caching the result of previous domain name lookups. Many platforms already can cache domain name lookups locally when appropriate, and they SHOULD be configured to do so. It is proper for these lookups to be cached, however, only when the TTL (Time To Live) information reported by the DNS makes it likely that the cached information will remain useful.

If implementations cache the results of domain name lookups in order to achieve a performance improvement, they MUST observe the TTL information reported by DNS. Implementations that fail to follow this rule could be spoofed or have access denied when a previously-accessed server's TLSA record changes, such as during a certificate rollover.

9. Acknowledgements

Many of the ideas in this document have been discussed over many years. More recently, the ideas have been discussed by the authors and others in a more focused fashion. In particular, some of the ideas and words here originated with Paul Vixie, Dan Kaminsky, Jeff Hodges, Phill Hallam-Baker, Simon Josefsson, Warren Kumari, Adam Langley, Ben Laurie, Ilari Liusvaara, Ondrej Mikle, Scott Schmit, Ondrej Sury, Richard Barnes, Jim Schaad, Stephen Farrell, Suresh Krishnaswamy, Peter Palfrader, Pieter Lexis, Wouter Wijngaards and John Gilmore.

This document has also been greatly helped by many active participants of the DANE Working Group.

[Appendix A.](#) Operational Considerations for Deploying TLSA Records

A.1. Creating TLSA Records

When creating TLSA records care must be taken to avoid misconfigurations. [Section 4](#) of this document states that a TLSA RRset whose validation state is secure MUST be used. This means that the existence of such a RRset effectively disables other forms of name and path validation. A misconfigured TLSA RRset will effectively disable access to the TLS server for all conforming clients, and this document does not provide any means of making a gradual transition to using TLSA.

When creating TLSA records with certificate usage type 0 (CA Certificate) or type 2 (Trust Anchor), one needs to understand the implications when choosing between selector type 0 (full certificate) and 1 (SubjectPublicKeyInfo). A careful choice is required because different methods for building trust chains are used by different TLS clients. The following outlines the cases that one should be aware of and discusses the implications of the choice of selector type.

Certificate usage 2 is not affected by the different types of chain building when the end entity certificate is the same as the trust anchor certificate.

A.1.1. Ambiguities and Corner Cases When TLS Clients Build Trust Chains

TLS clients may implement their own chain-building code rather than rely on the chain presented by the TLS server. This means that, except for the end entity certificate, any certificate presented in the suggested chain might or might not be present in the final chain built by the client.

Certificates that the client can use to replace certificates from original chain include:

- o Client's trust anchors
- o Certificates cached locally
- o Certificates retrieved from a URI listed in an Authority Information Access X.509v3 extension

CAs frequently reissue certificates with different validity period, signature algorithm (such as an different hash algorithm in the signature algorithm), CA key pair (such as for a cross-certificate), or PKIX extensions where the public key and subject remain the same. These reissued certificates are the certificates TLS client can use in place of an original certificate.

Clients are known to exchange or remove certificates that could cause TLSA association that rely on the full certificate to fail. For example:

- o The client considers the signature algorithm of a certificate to no longer be sufficiently secure
- o The client might not have an associated root certificate in its trust store and instead uses a cross-certificate with an identical subject and public key.

A.1.2. Choosing a Selector Type

In this section, "false-negative failure" means that a client will not accept the TLSA association for certificate designated by DNS administrator. Also, "false-positive acceptance" means that the client accepts a TLSA association for a certificate that is not designated by the DNS administrator.

A.1.2.1. Selector Type 0 (Full Certificate)

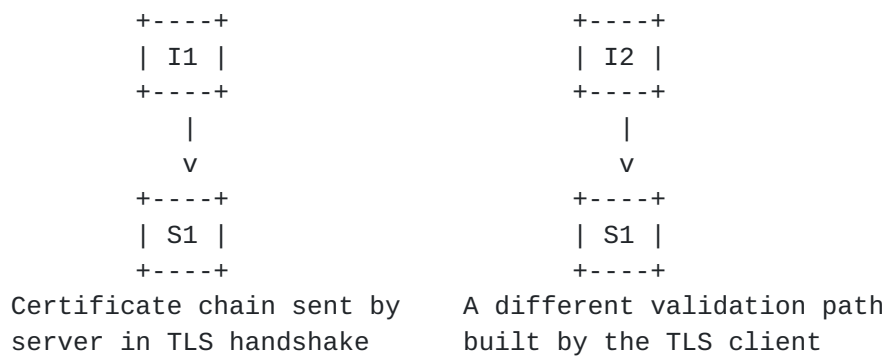

The "Full certificate" selector provides the most precise specification of a TLS certificate association, capturing all fields of the PKIX certificate. For a DNS administrator, the best course to avoid false-negative failures in the client when using this selector are:

- o If a CA issued a replacement certificate, don't associate to CA certificates that have a signature algorithm with a hash that is considered weak (such as MD2 and MD5).
- o Determine how common client applications process the TLSA association using a fresh client installation, that is, with the local certificate cache empty.

A.1.2.2. Selector Type 1 (SubjectPublicKeyInfo)

A SubjectPublicKeyInfo selector gives greater flexibility in avoiding some false-negative failures caused by trust-chain-building algorithms used in clients.

One specific use-case should be noted: creating a TLSA association to CA certificate I1 that directly signed end entity certificate S1 of the server. The case can be illustrated by following graph:

I2 is a reissued version of CA certificate I1 (that is, it has a different hash in its signature algorithm).

In the above scenario, both certificates I1 and I2 that sign S1 need to have identical SubjectPublicKeyInfos because the key used to sign S1 is fixed. An association to SubjectPublicKeyInfo (selector type 1) will always succeed in such a case, but an association with a full certificate (selector type 0) might not work due to a false-negative failure.

The attack surface is a bit broader compared to "full certificate" selector: the DNS administrator might unintentionally specify an association that would lead to false-positive acceptance.

- o The administrator must know or trust that the CA does not engage in bad practices, such as not sharing key of I1 for unrelated CA certificates leading to trust-chain redirect. If possible, the administrator should review all CA certificates that have the same SPKI.
- o The administrator should understand whether some PKIX extension may adversely affect security of the association. If possible, administrators should review all CA certificates that share the SubjectPublicKeyInfo.
- o The administrator should understand that any CA could, in the future, issue a certificate that contains the same SubjectPublicKeyInfo. Therefore, new chains can crop up in the future without any warning.

Using the SubjectPublicKeyInfo selector for association with a certificate in a chain above I1 needs to be decided on a case-by-case basis: there are too many possibilities based on the issuing CA's practices. Unless the full implications of such an association are understood by the administrator, using selector type 0 is a better option from a security perspective.

A.2. Provisioning TLSA Records in DNS

A.2.1. Provisioning TLSA Records with Aliases

The TLSA resource record is not special in the DNS; it acts exactly like any other RRtype where the queried name has one or more labels prefixed to the base name, such as the SRV RRtype [[RFC2782](#)]. This affects the way that the TLSA resource record is used when aliasing in the DNS.

Note that the IETF sometimes adds new types of aliasing in the DNS. If that happens in the future, those aliases might affect TLSA records, hopefully in a good way.

A.2.1.1. Provisioning TLSA Records with CNAME Records

Using CNAME to alias in DNS only aliases from the exact name given, not any zones below the given name. For example, assume that a zone file has only the following:

```
sub1.example.com.      IN CNAME sub2.example.com.
```

In this case, a request for the A record at "bottom.sub1.example.com" would not return any records because the CNAME given only aliases the name given. Assume, instead, the zone file has the following:

```
sub3.example.com.      IN CNAME sub4.example.com.  
bottom.sub3.example.com. IN CNAME bottom.sub4.example.com.
```

In this case, a request for the A record at bottom.sub3.example.com would in fact return whatever value for the A record exists at bottom.sub4.example.com.

Application implementations and full-service resolvers request DNS records using libraries that automatically follow CNAME (and DNAME) aliasing. This allows hosts to put TLSA records in their own zones or to use CNAME to do redirection.

If the owner of the original domain wants a TLSA record for the same, they simply enter it under the defined prefix:

```
; No TLSA record in target domain  
;  
sub5.example.com.      IN CNAME sub6.example.com.  
_443._tcp.sub5.example.com. IN TLSA 1 1 1 308202c5308201ab...  
sub6.example.com.      IN A 192.0.2.1  
sub6.example.com.      IN AAAA 2001:db8::1
```

If the owner of the original domain wants to have the target domain host the TLSA record, the original domain uses a CNAME record:

```
; TLSA record for original domain has CNAME to target domain
;
sub5.example.com.          IN CNAME sub6.example.com.
_443._tcp.sub5.example.com. IN CNAME _443._tcp.sub6.example.com.
sub6.example.com.          IN A 192.0.2.1
sub6.example.com.          IN AAAA 2001:db8::1
_443._tcp.sub6.example.com. IN TLSA 1 1 1 536a570ac49d9ba4...
```

Note that it is acceptable for both the original domain and the target domain to have TLSA records, but the two records are unrelated. Consider the following:

```
; TLSA record in both the original and target domain
;
sub5.example.com.          IN CNAME sub6.example.com.
_443._tcp.sub5.example.com. IN TLSA 1 1 1 308202c5308201ab...
sub6.example.com.          IN A 192.0.2.1
sub6.example.com.          IN AAAA 2001:db8::1
_443._tcp.sub6.example.com. IN TLSA 1 1 1 ac49d9ba4570ac49...
```

In this example, someone looking for the TLSA record for sub5.example.com would always get the record whose value starts "308202c5308201ab"; the TLSA record whose value starts "ac49d9ba4570ac49" would only be sought by someone who is looking for the TLSA record for sub6.example.com, and never for sub5.example.com. One should note that deploying different certificates for multiple services located at a shared TLS listener often requires the use of TLS SNI (Server Name Indication) [[RFC6066](#)].

Note that these methods use the normal method for DNS aliasing using CNAME: the DNS client requests the record type that they actually want.

[A.2.1.2.](#) Provisioning TLSA Records with DNAME Records

Using DNAME records allows a zone owner to alias an entire subtree of names below the name that has the DNAME. This allows the wholesale aliasing of prefixed records such as those used by TLSA, SRV, and so on without aliasing the name itself. However, because DNAME can only be used for subtrees of a base name, it is rarely used to alias individual hosts that might also be running TLS.

```
; TLSA record in target domain, visible in original domain via DNAME
;
sub5.example.com.          IN CNAME sub6.example.com.
_tcp.sub5.example.com.    IN DNAME _tcp.sub6.example.com.
sub6.example.com.         IN A 192.0.2.1
sub6.example.com.         IN AAAA 2001:db8::1
_443._tcp.sub6.example.com. IN TLSA 1 1 1 536a570ac49d9ba4...
```

[A.2.1.3.](#) Provisioning TLSA Records with Wildcards

Wildcards are generally not terribly useful for RRtypes that require prefixing because you can only wildcard at a layer below the host name. For example, if you want to have the same TLSA record for every TCP port for `www.example.com`, you might have

```
*._tcp.www.example.com.    IN TLSA 1 1 1 5c1502a6549c423b...
```

This is possibly useful in some scenarios where the same service is offered on many ports.

[A.3.](#) Securing the Last Hop

As described in [Section 4](#), an application processing TLSA records must know the DNSSEC validity of those records. There are many ways for the application to securely find this out, and this specification does not mandate any single method.

Some common methods for an application to know the DNSSEC validity of TLSA records include:

- o The application can have its own DNS resolver and DNSSEC validation stack.
- o The application can communicate through a trusted channel (such as requests to the operating system under which the application is running) to a local DNS resolver that does DNSSEC validation.
- o The application can communicate through a secured channel (such as requests running over TLS, IPsec, TSIG or SIG(0)) to a non-local DNS resolver that does DNSSEC validation.
- o The application can communicate through a secured channel (such as requests running over TLS, IPsec, TSIG or SIG(0)) to a non-local DNS resolver that does not do DNSSEC validation, but gets responses through a secured channel from a different DNS resolver that does DNSSEC validation.

A.4. Handling Certificate Rollover

Certificate rollover is handled in much the same way as for rolling DNSSEC zone signing keys using the pre-publish key rollover method [[RFC4641](#)]. Suppose example.com has a single TLSA record for a TLS service on TCP port 990:

```
_990._tcp.example.com IN TLSA 1 1 1 1CFC98A706BCF3683015...
```

To start the rollover process, obtain or generate the new certificate or SubjectPublicKeyInfo to be used after the rollover and generate the new TLSA record. Add that record alongside the old one:

```
_990._tcp.example.com IN TLSA 1 1 1 1CFC98A706BCF3683015...
_990._tcp.example.com IN TLSA 1 1 1 62D5414CD1CC657E3D30...
```

After the new records have propagated to the authoritative nameservers and the TTL of the old record has expired, switch to the new certificate on the TLS server. Once this has occurred, the old TLSA record can be removed:

```
_990._tcp.example.com IN TLSA 1 1 1 62D5414CD1CC657E3D30...
```

This completes the certificate rollover.

Appendix B. Pseudocode for Using TLSA

This appendix describes the interactions given earlier in this specification in pseudocode format. This appendix is non-normative. If the steps below disagree with the text earlier in the document, the steps earlier in the document should be considered correct and this text incorrect.

Note that this pseudocode is more strict than the normative text. For instance, it forces an order on the evaluation of criteria which is not mandatory from the normative text.

B.1. Helper Functions

```
// implement the function for exiting
function Finish (F) = {
  if (F == ABORT_TLS) {
    abort the TLS handshake or prevent TLS from starting
    exit
  }
}
```

```
if (F == NO_TLSA) {
    fall back to non-TLSA certificate validation
    exit
}

if (F == ACCEPT) {
    accept the TLS connection
    exit
}

// unreachable
}

// implement the selector function
function Select (S, X) = {
    // Full certificate
    if (S == 0) {
        return X in DER encoding
    }

    // SubjectPublicKeyInfo
    if (S == 1) {
        return X.SubjectPublicKeyInfo in DER encoding
    }

    // unreachable
}

// implement the matching function
function Match (M, X, Y) {
    // Exact match on selected content
    if (M == 0) {
        return (X == Y)
    }

    // SHA-256 hash of selected content
    if (M == 1) {
        return (SHA-256(X) == Y)
    }

    // SHA-512 hash of selected content
    if (M == 2) {
        return (SHA-512(X) == Y)
    }

    // unreachable
}
```

B.2. Main TLSA Pseudo Code

TLS connect using [transport] to [name] on [port] and receiving end entity cert C for the TLS server:

```
(TLSArecords, ValState) = DNSSECValidatedLookup(
    domainname=_[port]._[transport].[name], RRtype=TLSA)

// check for states that would change processing
if (ValState == BOGUS) {
    Finish(ABORT_TLS)
}
if ((ValState == INDETERMINATE) or (ValState == INSECURE)) {
    Finish(NO_TLSA)
}
// if here, ValState must be SECURE

for each R in TLSArecords {
    // unusable records include unknown certUsage, unknown
    // selectorType, unknown matchingType, erroneous RDATA, and
    // prohibited by local policy
    if (R is unusable) {
        remove R from TLSArecords
    }
}
if (length(TLSArecords) == 0) {
    Finish(NO_TLSA)
}

// A TLS client might have multiple trust anchors that it might use
// when validating the TLS server's end entity certificate. Also,
// there can be multiple PKIX certification paths for the
// certificates given by the server in TLS. Thus, there are
// possibly many chains that might need to be tested during
// PKIX path validation.

for each R in TLSArecords {

    // pass PKIX certificate validation and chain through a CA cert
    // that comes from TLSA
    if (R.certUsage == 0) {
        for each PKIX certification path H {
            if (C passes PKIX certification path validation in H) {
                for each D in H {
                    if ((D is a CA certificate) and
                        Match(R.matchingType, Select(R.selectorType, D),
                            R.cert)) {
```

```
        Finish(ACCEPT)
    }
}
}

// pass PKIX certificate validation and match EE cert from TLSA
if (R.certUsage == 1) {
    for each PKIX certification path H {
        if ((C passes PKIX certificate validation in H) and
            Match(R.matchingType, Select(R.selectorType, C),
                R.cert)) {
            Finish(ACCEPT)
        }
    }
}

// pass PKIX certification validation using TLSA record as the
// trust anchor
if (R.certUsage == 2) {
    for each PKIX certification path H that has R as the
        trust anchor {
        if (C passes PKIX certification validation in H) and
            Match(R.matchingType, Select(R.selectorType, C),
                R.cert)) {
            Finish(ACCEPT)
        }
    }
}

// match the TLSA record and the TLS certificate
if (R.certUsage == 3) {
    if Match(R.matchingType, Select(R.selectorType, C), R.cert)
        Finish(ACCEPT)
}

}

// if here, then none of the TLSA records ended in "Finish(ACCEPT)"
// so abort TLS
Finish(ABORT_TLS)
```

[Appendix C](#). Examples

The following are examples of self-signed certificates that have been generated with various selectors and matching types. They were generated with one piece of software, and validated by an individual using other tools.

S = Selector

M = Matching Type

S M Association Data
