A real-time stream control protocol (RTSP')

STATUS OF THIS MEMO

ABSTRACT

       This strawman proposal presents a revised version of the
       RTSP proposal put forward to the MMUSIC group, borrowing
       liberally from the original.

       The Real Time Streaming Protocol, or RTSP, is an
       application-level protocol for control over the delivery
       of data with real-time properties. RTSP provides an
       extensible framework to enable controlled, on-demand
       delivery of real- time data, such as audio and video.
       Sources of data can include both live data feeds and
       stored clips. This protocol is intended to control
       multiple data delivery sessions, provide a means for
       choosing delivery channels such as UDP, multicast UDP and

            TCP, and delivery mechanisms based upon RTP ([RFC 1889]).

[1] Introduction

[1.1] Terminology

    conference: a multiparty, multimedia session, where "multi" implies
         greater than or equal to one.

    client: The client requests media data from the media server.

    entity: An entity is a participant in a conference. This participant
         may be non-human, e.g., a media record or playback server.

    media server: The network entity providing playback or recording
         services for one or more media streams. Different media streams
         within a session may originate from different media servers. A
         media server may reside on the same or a different host as the
         web server the media session is invoked from.

    (media) stream: A single media instance, e.g., an audio stream or a
         video stream as well as a whiteboard or shared application
         session. When using RTP, a stream consists of all RTP and RTCP
         packets created by a source within an RTP session.

    [TBD: terminology is confusing since there's an RTP session, which is
    used by a single RTSP stream.]

    media session: A collection of media streams to be treated.
         Typically, a client will synchronize all media streams within a
         media session.

    session description: A session description contains information about
         one or more media within a session, such as the set of
         encodings, network addresses and information about the content.
         The session description may take several different formats,
         including SDP and SDF.

    Both client and server can send commands.

    The protocol supports the following operations:

    Retrieval of media from media server: The client can request a
         session decription via HTTP or some other method. If the session
         is being multicast, the session description contains the
         multicast addresses and ports to be used. If the session is to
         be sent only to the client, the client provides the destination

for security reasons.

H. Schulzrinne   [Page 2]

    Invitation of media server to conference: A media server can be
        "invited" to join an existing conference, either to play back
        media into the session or to record all or a subset of the media
        in a session. This mode is useful for distributed teaching
        applications. Several parties in the conference may take turns
        "pushing the remote control buttons".

    Adding media to an existing session: Particularly for live events, it
        is useful if the server can tell the client about additional
        media becoming available.

1.2 Requirements

    The protocol satisfies the following requirements

    extendable: new commands and parameters can be easily added

    easy to parse: standard HTTP or MIME parsers can (but do not have to
        be) used

    secure: re-uses web security mechanisms, either at the transport
        level (SSL) or within the requests (basic and digest
        authentication)

    transport-independent: may use either an unreliable datagram protocol
        (UDP), a reliable datagram protocol (RDP, not widely used) or a
        reliable stream protocol (TCP) by implementing application-level
        reliability

    multi-server capable: Each media stream within a session can reside
        on a different server. The client automatically establishes
        several concurrent control sessions with the different media
        servers. Media synchronization is performed at the transport
        level.

    multi-client capable: Stream identifiers can be used by several
        control streams, so that "passing the remote" is possible. The
        protocol does not address how several clients negotiate access;
        this is left to either a "social protocol" or some other floor
        control mechanism.

control of recording devices: The protocol can control both recording
    and playback devices, as well as devices that can alternate
    between the two modes ("VCR").

separation of stream control and conference initiation: Stream
    control is divorced from inviting a media server to a
    conference. The only requirement is that the conference

initiation protocol either provides or can be used to create a
    unique conference identifier. In particular, S*IP or H.323 may
    be used to invite a server to a conference.

suitable for professional applications: RTSP' supports frame-level
    accuracy through SMPTE time stamps to allow remote digital
    editing.

S*IP compatible: As much as possible, stream control should be
    aligned with the IETF conference initiation effort. However, for
    simple applications, a media server should not have to implement
    a conference initiation protocol.

session description neutral: The protocol does not impose a
    particular session description or metafile format and can convey
    the type of format to be used. However, the session description
    must contain an RTSP URI.

proxy and firewall friendly: The protocol should be readily handled
    by both application and transport-layer (SOCKS) firewalls. For
    proxies, re-use of existing proxies should be possible, but
    remains to be verified. [TBD: what exactly is needed to make a
    protocol firewall-friendly?] A firewall may need to understand
    the SET_PORT directive to open a "hole" for the UDP media
    stream.

HTTP friendly: Where sensible, RTSP re-uses HTTP concepts, so that
    the existing infrastructure can be re-used.

1.3 Extending the Protocol

The protocol described below can be extended in three ways, listed in
order of the magnitude of changes supported:

o Existing commands can be extended with new parameters, as long
  as these parameters can be safely ignored by the recipient.
  (This is equivalent to adding new parameters to an HTML tag.)

o New methods can be added. If the recipient of the message does
  not understand the request, it responds with error code 501
  (Not implemented) and the sender can then attempt an earlier,
  less functional version.

o A new version of the protocol can be defined, allowing almost
  all aspects (except the position of the protocol version
  number) to change.

1.4 Overall Operation

Each media stream and session is identified by an rtsp URL. The
overall session and the properties of the media the session is made
up of are defined by a session description file, the format of which
is outside the scope of this specification. The session description
file is retrieved using HTTP, either from the web server or the media
server, typically using an URL with scheme http.

The session description file contains a description of the media
streams making up the media session, including their encodings,
language, and other parameters that enable the client to choose the
most appropriate combination of media. In this session description,
each media stream is identified by an rtsp URL, which points to the
media server handling that particular media stream. Several media
streams can be located on different servers; for example, audio and
video tracks can be split across servers for load sharing. The
description also enumerates which transport methods the server is
capable of. If desired, the session description can also contain only
an RTSP URL, with the complete session description retrieved via
RTSP.

Besides the media parameters, the network destination address and
port need to be determined. Several modes of operation can be
distinguished:

Unicast: The media is transmitted to the source of the RTSP request,
     with the port number picked by the client. Alternatively, the

media is transmitted on the same reliable stream as RTSP.

   Multicast, server chooses address: The media server picks the
        multicast address and port. This is the typical case for a live
        or near-media-on-demand transmission.

   Multicast, client chooses address: If the server is to participate in
        an existing multicast conference, the multicast address, port
        and encryption key are given by the conference.

1.5 Relationship with Other Protocols

   RTSP' has some overlap in functionality with HTTP. It also needs to
   interact with the web in that the initial contact with streaming
   content is often to be made through a web page. The current protocol
   specification aims to allow different hand-off points between a web
   server and the media server implementing RTSP'. For example, the
   session description can be retrieved using HTTP or RTSP'. Having the
   session description be returned by the web server makes it possible
   to have the web server take care of authentication and billing, by
   handing out a session description whose media identifier includes an
   encrypted version of the requestor's IP address and a timestamp, with

   a shared secret between web and media server.

   However, RTSP' differs fundamentally from HTTP in that data delivery
   takes place out-of-band, in a different protocol. HTTP is an
   asymmetric protocol, where the client issues requests and the server
   responds. In RTSP', both the media client and media server can issue
   requests. RTSP' requests are also not stateless, in that they may set
   parameters and continue to control a media stream long after the
   request has been acknowledged.

        Re-using HTTP functionality has advantages in at least two
        areas, namely security and proxies. The requirements are
        very similar, so having the ability to adopt HTTP work on
        caches, proxies and authentication is valuable. The current
        RTSP already has first hints on caches and proxies, but is
        nowhere near as complete as HTTP in that regard.

   It is possible to very quickly build a simple RTSP' server by adding

a PLAY and, optionally, a SET_PARAMETER method to an existing
HTTP/1.1 web server. All of RTSP' can be implemented as part of an
HTTP server as long as only the client issues requests.

While most real-time media will use RTP as a transport protocol,
RTSP' is not tied to RTP.

RTSP' assumes the existence of a session description format that can
express both static and temporal properties of a media session
containing several media streams.

2 Protocol Parameters

2.1 Message Format and Transmission

RTSP is a text-based protocol [TBD] and uses the ISO 10646 character
set in UTF-8 encoding (RFC 2044) [TBD; this conflicts with]. Lines
are terminated by CRLF, but receivers should be prepared to also
interpret CR and LF by themselves as line terminators.

Text-based protocols make it easier to add optional
parameters in a self-describing manner. Since the number of
parameters and the frequency of commands is low, processing
efficiency is not a concern. Text-based protocols, if done
carefully, also allow easy implementation in scripting
languages such as Tcl, VisualBasic and Perl.

The 10646 character set avoids tricky character set switching, but is
invisible to the application as long as US-ASCII is being used. This

is also the encoding used for RTCP. ISO 8859-1 translates directly
into Unicode, with a high-order octet of zero. ISO 8859-1 characters
with the most-significant bit set are represented as 1100001x
10xxxxxx.

RTSP messages can be carried over any lower-layer transport protocol
that is 8-bit clean.

Commands are acknowledged by the receiver unless they are sent to a
multicast group. If there is no acknowledgement, the sender may
resend the same message after a timeout of one round-trip time (RTT).
The round-trip time is estimated as in TCP (RFC TBD), with an initial

round-trip value of 500 ms. An implementation MAY cache the last RTT
measurement as the initial value for future connections. If a
reliable transport protocol is used to carry RTSP, the timeout value
MAY be set to an arbitrarily large value.

> This can greatly increase responsiveness for proxies
> operating in local-area networks with small RTTs. The
> mechanism is defined such that the client implementation
> does not have be aware of whether a reliable or unreliable
> transport protocol is being used. It is probably a bad idea
> to have two reliability mechanisms on top of each other,
> although the RTSP RTT estimate is likely to be larger than
> the TCP estimate.

Each request carries a sequence number, which is incremented by one
for each request transmitted. If a request is repeated because of
lack of acknowledgement, the sequence number is incremented.

> This avoids ambiguities when computing round-trip time
> estimates. [TBD: An initial sequence number negotiation
> needs to be added for UDP; otherwise, a new stream
> connection may see a request be acknowledged by a delayed
> response from an earlier "connection". This handshake can
> be avoided with a sequence number containing a timestamp of
> sufficiently high resolution.]

The reliability mechanism described here does not protect against
reordering. This may cause problems in some instances. For example, a
STOP followed by a PLAY has quite a different effect than the
reverse. Similarly, if a PLAY request arrives before all parameters
are set due to reordering, the media server would have to issue an
error indication. Since sequence numbers for retransmissions are
incremented (to allow easy RTT estimation), the receiver cannot just
ignore out-of-order packets. [TBD: This problem could be fixed by
including both a sequence number that stays the same for
retransmissions and a timestamp for RTT estimation.]

Systems implementing RTSP MUST support carrying RTSP over TCP and MAY
support UDP. The default port for the RTSP server is [PORT] for both
UDP and TCP.

A number of RTSP packets destined for the same control end point may

be packed into a single lower-layer PDU or encapsulated into a TCP
stream. RTSP data MAY be interleaved with RTP and RTCP packets. An
RTSP packet is terminated with an empty line. (TBD: doesn't work well
for including session descriptions. Maybe use Content-length for
payloads - these are usually imported anyway? or new page? Wrapping a
packet in some kind of braces or parenthesis is another possibility,
but again puts restrictions on the SDF.)

     Unless all but the RTP data is textual, there is not much
     point in keeping the payload as textual data, since visual
     debugging is more difficult and "telnet protocol emulation"
     is no longer possible. Length fields don't make much sense
     for textual data, particularly because of the line
     termination ambiguities, i.e., CR, LF and CRLF. There does
     not seem to be a need for an explicit, connection-oriented
     framing layer as in the original RTSP proposal. However, if
     we allow interleaving with RTP, a textual format gets very
     awkward.

Requests contain methods, the object the method is operating upon and
parameters to further describe the method. Methods are idempotent,
unless otherwise noted. Methods are also designed to require little
or no state maintenance at the media server.

A message has the following format:

Method Object Version Sequence-Number
*(Parameter-Value)
CRLF

A message with a message body has the following format:

Method Object Version Sequence-Number
Content-length:
*(Parameter-Value)
CRLF
message-body

After receiving and interpreting an RTSP' request, the server
responds with an RTSP' response message.

[TBD: proper BNF]

A typical response to a request with sequence number 17 might be:

RTSP/1.0 200 17 OK

This format is HTTP-friendly; the sequence number is simply
ignored by HTTP servers. The likelihood that a textual
protocol will share the same port and not have that format
seems fairly remote. RTP packets have the most-significant
bit set and can thus be easily distinguished.

If a connectionless transport protocol is used, the media server
considers all packets originating from a single port number and
network address to be part of the same session. [TBD: is this
necessary?]

2.2 Session and Media URI

The RTSP URL scheme is used to locate and control stream resources
via the RTSP protocol.

A media stream is identified by an textual session and media
identifier, using the character set and escape conventions of URLs.
The media identifier is separated from the session by a slash.
Commands below can refer to either the whole session or an individual
stream. Stream identifiers can be passed between clients ("passing
the remote control"). A specific instance of a session, e.g., one of
several concurrent transmissions of the same content, is appended
where needed. The instance identifies the whole session, so that all
media streams within that session have the same instance identifier.

For example,

rtsp://media.content.com:5000/twister/audio.en/1234

identifies instance 1234 of the stream audio.en within the session
"twister", which is located at port 5000 of host media.content.com.

The ordering and significance of the path components of the rtsp URL
is only of significance to the media server.

   This decoupling also allows session descriptions to be used
   with non-RTSP media control protocols, simply by replacing
   the scheme in the URL.

2.3 Encoding Identifiers

RTP profile and/or MIME types. [TBD: should probably register all the
RTP data types as MIME types.]

2.4 Conference Identifiers

Conference identifiers are opaque to RTSP' and are encoded using
standard URI encoding methods (i.e., escaping with %). They can
contain any octet value. The conference identifier MUST be globally
unique. For H.323, the conferenceID value is to be used.

   If the conference participant inviting the media server
   would only supply a conference identifier which is unique
   for that inviting party, the media server could add an
   internal identifier for that party, e.g., its Internet
   address. However, this would prevent that the conference
   participant and the initiator of the RTSP commands are two
   different entities.

2.5 Relative Timestamps

A relative time-stamp expresses time relative to the start of the
clip. Relative timestamps are expressed as SMPTE time codes for
frame-level access accuracy. The time code has the format
hours:minutes:seconds.frames, with the origin at the start of the
clip. For NTSC, the frame rate is 29.97 frames per second. This is
handled by dropping the first frame index of every minute, except
every tenth minute. If the frame value is zero, it may be omitted.

Examples:

```
10:12:33.40
10:7:33
```

2.6 Absolute Time

Absolute time is expressed as ISO 8601 timestamps. It is always
expressed as UTC (GMT).

Example for November 8, 1996 at 14h37 and 20 seconds GMT:

```
19961108T143720Z
```

3 Header Field Definitions

3.1 Accept

The Accept request-header field can be used to specify certain
session description types which are acceptable for the response. The
only parameter allowed is that of level , which indicates the highest
level or version accepted by the requestor.

Example of use:

```
Accept: application/sdf, application/sdp;level=2
```

3.2 Address

3.3 Allow

The Allow response header field lists the methods supported by the
resource identified by the Request-URI. The purpose of this field is
to strictly inform the recipient of valid methods associated with the
resource. An Allow header field must be present in a 405 (Method not
allowed) response.

Example of use:

Allow: PLAY, RECORD, SET_PARAMETER

   This field establishes a logical connection between a conference,
   established using non-RTSP' means, and an RTSP stream.

   [TBD: This parameter is for further study. May not be needed with the
   Given parameter.]

   The Method token indicates the method to be performed on the resource
   identified by the Request-URI case-sensitive. New methods may be

defined in the future. Method names may not start with a $ character
(decimal 24) and must be a token

4.1 GET

The GET method retrieves a session description from a server. It may
use the Accept header to specify the session description formats that
the client understands.

```
GET twister RTSP/1.0 937
Accept: application/sdp, application/sdf, application/mheg
```

If the media server has previously been invited to a conference, the
GET method also contains a conference identifier or a Given
parameter.

```
GET twister RTSP/1.0 834
Conference: 128.16.64.19/32492374
Authorization: Basic QWxhZGRpbjpvcGVuIHNlc2FTZQ==
```

If the GET request contains a conference identifier, the media server
MUST locate the conference description and use the multicast
addresses and port numbers supplied in that description. The media
server SHOULD only offer media types corresponding to the media types
currently active within the conference. If the media server has no
local reference to this conference, it returns status code 452.

The conference invitation should also contain an indication whether
the media server is expected to receive or generate media, or both.
(A VCR-like device would support both directions.) If the invitation
does not contain an indication of the operations to be performed, the
media server should accept and then reject inappropriate operations.

A typical response might be:

```
200 18 OK
Content-Type: application/sdf
session description
```

4.2 SESSION

This method is used by a media server to send media information to
the client. If a new media type is added to a session (e.g., during a
live event), the whole session description should be sent again,
rather than just the additional components.

   This allows the deletion of session components.

Example:

```
SESSION twister/*/1234 Content-Type: application/sdp
```

Session Description

Response: 200, 302, 303, 500, can't do this operation, busy,

4.3 PLAY

The PLAY method tells the server to start sending data via the
previously set transport mechanism. The Range header specifies the
range. The range can be specified in a number of units. This
specification defines the smpte (see Section 2.5) and clock (see

Section 2.6) range units.

```
PLAY media-name
Range: smpte= range-value
```

The following example plays the whole session starting at SMPTE time
code 0:10:20 until the end of the clip.

```
PLAY twister/*/1234
Range: smpte=0:10:20-
```

For playing back a recording of a live event, it may be desirable to
use clock units:

   PLAY meeting/*/1234
   Range: clock=19961108T142300Z-19961108T143520Z

   A media server only supporting playback MUST support the smpte format
   and MAY support the clock format.

   [TBD: It may be desirable to allow several ranges, so that remote
   digital editing can be done easily.]

   Response: 200, 500, 501, clock format not supported.

4.4 RECORD

   This method initiates eecording a range of media data according to
   the session description. The timestamp reflects start and end time
   (UTC). If no time range is given, use the start or end time provided
   in the session description. If the session has already started,
   commence recording immediately. The Conference header is mandatory.

   A media server supporting recording of live events MUST support the
   clock range format; the smpte format does not make sense.

   RECORD meeting/audio.en/1234
   Conference: 128.16.64.19/32492374

4.5 REDIRECT

   A redirect request informs the client that it must connect to another
   server location. It contains the mandatory header Location , which
   indicates that the client should issue a GET for that URL. It may
   contain the parameter Range , which indicates when the redirection
   takes effect.

[4.6](#) SET_PARAMETER

   Both client and media server can issue this request.

   The following parameters are defined:

   Blocksize: This advisory parameter is sent from the client to the
       media server setting the transport packet size. The server
       truncates this packet size to the closest multiple of the
       minimum media-specific block size or overrides it with the media
       specific size if necessary. The block size is a strictly
       positive decimal number and measured in bytes. The server only
       returns an error (416) if the value is syntactically invalid,
       but not if the server adjusts it according to the mechanism
       described above or decides to simply ignore the advice.

   Port: UDP or TCP port to be used for this media.

   SSRC: RTP SSRC value to be used by the media server. This parameter
       is only valid for unicast transmission. It identifies the
       synchronization source to be associated with the media stream.
       This can be used for demultiplexing by the client of data
       received on the same port.

   Address: Destination network address, consisting of the address class
       identifier and the address. Currently, the address classes IP4
       and IP6 are defined.

   Transport: Transport protocol stack to be used: UDP or TCP or
       interleaved, followed by the next-layer transport protocol. in
       whatever protocol is being used by the control stream.
       Currently, the next-layer protocols RTP is defined. Parameters
       may be added to each protocol, separated by a semicolon. For
       RTP, the boolean parameter compressed is defined, indicating
       compressed RTP according to RFC XXXX. Example: UDP
       RTP;compressed

   TTL: Multicast time-to-live value. In some cases, it may make sense
       for a client to ask a media server sending on a given multicast
       address to expand its range.

H. Schulzrinne   [Page 15]

Speed: This advisory parameter sets the speed at which the server
      delivers data to the client, contingent on the server's ability
      and desire to serve the media stream at the given speed.
      Implementation by the server is optional. The default is the bit
      rate of the stream.

The parameter value is expressed as a decimal ratio, e.g., 2.0
indicates that data is to be delivered twice as fast as normal. A
speed of zero is invalid. A negative value indicates that the stream
is to be played back in reverse direction.

A request SHOULD only contain a single parameter to allow the client
to determine why a particular request failed. A server MUST allow a
parameter to be set repeatedly to the same value, but it MAY disallow
changing parameter values.

      The parameters are split in a fine-grained fashion so that,
      for example, the client can set just the unicast port,
      without having to modify the destination address. There is
      no substantial difference between the privileged parameters
      and the parameters identified by family and parameter id in
      the current RTSP spec. If desired, parameter names could
      easily take the form family/parameter , e.g.,
      Audio/Annotations

A SET_PARAMETER request without parameters can be used as a way to
detect whether the other side is still responding.

Example:

SET_PARAMETER twister/1234/audio.en RTSP/1.0 68
Speed: 2.3

[TBD: Or should this be like SET_PARAMETER? Bit longer, but forces
single parameter per request.]

4.7 GET_PARAMETER

Both client and media server can issue a GET_PARAMETER request to
retrieve a specific parameter. All parameters described for the
SET_PARAMETER request are valid. In the request, the message body
contains the parameter value. Only one parameter can be requested in
each GET_PARAMETER request.

Example:

C->S: GET_PARAMETER twister/1234/audio.en RTSP/1.0 6
      Content-length: 17

      Audio/Annotations

S->C: RTSP/1.0 200 6 OK
      Content-type: text/ascii
      Content-length: 2

      64

4.8 STOP

Stops delivery of stream immediately. Returns indication of current
position to allow play instead of resume.

    Thus, RESUME is not needed.

C->M: STOP movie RTSP/1.0 76

M->C: RTSP/1.0 200 76 OK

4.9 BYE

Sent by either client or server to terminate a connection and release
resources.

4.10 Embedded Data Stream

The command DATA is used to indicate an embedded media data object,
together with the content types. DATA requests are not acknowledged
by RTSP'. The embedded object can have any type. For space-efficient
encapsulation of binary data, the method in Section 4.11 should be
used instead.

```
DATA twisters/audio.en/1234 RTSP/1.1
Content-Length: 500
```

```
Content-Type: message/rtp

(RTP data)
```

>   This is workable, but not very space-efficient. However,
>   the interesting case is that of a single TCP stream
>   carrying both commands and media data. There is no
>   particular reason to have small chunks in that case.

4.11 Embedded Binary Data

Binary packets such as RTP data are encapsulated by an ASCII dollar
sign (24 decimal), followed by a one-byte session identifier,
followed by the length of the encapsulated binary data as a binary,
two-byte integer in network byte order. The binary data follows
immediately afterwards, without a CRLF.

>   This makes the encapsulation overhead 4 bytes, less than
>   the 8 bytes imposed by SCP.

5 Status Codes Definitions

Where applicable, HTTP status codes are re-used. [TBD: add those
relevant here]

5.1 Successful 2xx

5.1.1 200 OK

The request has succeeded. The information returned with the response
depends on the method used in the request, for example:

GET: the session description;

GET_PARAMETER: the value of the parameter.

5.2 Redirection 3xx

5.3 Client Error 4xx

5.3.1 400 Bad Request

The request could not be understood by the recipient due to malformed
syntax. The request SHOULD NOT be repeated without modification.

5.3.2 401 Unauthorized

The request requires user authentication.

5.3.3 402 Payment Required

This code is reserved for future use.

5.3.4 405 Method Not Allowed

5.3.5 406 Not Acceptable

5.3.6 408 Request Timeout

5.3.7 411 Length Required

5.3.8 414 Request URI Too Long

5.3.9 415 Unsupported Mediatype

The recipient of the request is refusing to service the request
because the entity of the request is in a format not supported by the
requested resource for the requested method.

   The parameter in the request is not valid, i.e., out of range or
   malformed.

   The recipient of the request does not support one or more parameters
   contained in the request.

   The conference indicated by a Conference: identifier is unknown to
   the media server.

   The request was refused since there was insufficient bandwidth. This
   may, for example, be the result of a resource reservation failure.

   The server is currently unable to handle the request due to a
   temporary overloading or maintenance of the server. The implication
   is that this is a temporary condition which will be alleviated.

Client C requests a movie media servers A (audio.content.com) and V
(video.content.com). The media description is stored on a web server
W. This, however, is transparent to the client. The client is only
interested in the last part of the movie. The server requires
authentication for this movie. The audio track can be dynamically
switched between between two sets of encodings. The URL with scheme
rtpsu indicates the media servers want to use UDP for exchanging RTSP
messages.

```
C->W: GET twister HTTP/1.0
      Accept: application/sdf; application/sdp

W->C: 200 OK
      Content-type: application/sdf

      (session
        (all
          (media (t audio) (oneof
             ((e PCMU/8000/1 89 DVI4/8000/1 90) (id lofi))
             ((e DVI4/16000/2 90 DVI4/16000/2 91) (id hifi))
            )
            (language en)
            (id rtspu://audio.content.com/twister/audio.en/1234)
            )
```

```
          (media (t video) (e JPEG)
            (id rtspu://video.content.com/twister/video/1234)
          )
        )
      )

C->A: SET_PARAMETER twister/audio.en/1234/lofi RTSP/1.0 1
      Port: 3056
      Transport: RTP;compression

A->C: RTSP/1.0 200 1 OK

C->V: SET_PARAMETER twister/video/1234/hifi RTSP/1.0 2
      Port: 3058
      Transport: RTP;compression
```

```
V->C: RTSP/1.0 200 2 OK

C->V: PLAY twister/video/1234 RTSP/1.0 3
      Range: smpte 0:10:00-

V->C: RTSP/1.0 200 3 OK

C->A: PLAY twister/audio.en/1234/lofi RTSP/1.0 4
      Range: smpte 0:10:00-

S->C: 200 4 OK
```

Even though the audio and video track are on two different servers,
may start at slightly different times and may drift with respect to
each other, the client can synchronize the two using standard RTP
methods.

[6.2](#) Live Media Event Using Multicast

The media server chooses the multicast address and port. Here, we
assume that the web server only contains a pointer to the full
description, while the media server M maintains the full description.
During the session, a new subtitling stream is added.

```
C->W: GET concert HTTP/1.0

W->C: HTTP/1.0 200 OK
      Content-Type: application/sdf
```

```
      (session
        (id rtsp://live.content.com/concert)
      )

C->M: GET concert RTSP/1.0 1

M->C: RTSP/1.0 200 OK
      Content-Type: application/sdf
```

```
              (session (all
                (media (t audio) (id music) (a IP4 224.2.0.1) (p 3456))
              ))

   C->M: PLAY concert/music RTSP/1.0
         Range: smpte 1:12:0

   M->C: RTSP/1.0 405 No positioning possible

   M->C: SESSION concert RTSP/1.0
         Content-Type: application/sdf

              (session (all
                (media (t audio) (id music))
                (media (t text) (id lyrics))
              ))

   C->M: PLAY concert/lyrics RTSP/1.0
```

   Since the session description already contains the necessary address
   information, the client does not set the transport address. The
   attempt to position the stream fails since this is a live event.

6.3 Playing media into an existing session

   A conference participant C wants to have the media server M play back
   a demo tape into an existing conference. When retrieving the session
   description, C indicates to the media server that the network
   addresses and encryption keys are already given by the conference, so
   they should not be chosen by the server. The example omits the simple
   ACK responses.

```
   C->M: GET demo RTSP/1.0 1
         Accept: application/sdf, application/sdp
         Given: address, privacy
```

```
   M->C: RTSP/1.0 200 1 OK
```

```
                Content-type: application/sdf

                (session
                    (id 548)
                    (media (t audio) (id sound)
                )

    C->M: SET_PARAMETER demo/548/sound RTSP/1.0 2
          Address: IP4 224.2.0.1
          Port:    3456
          TTL:     127
```

Recording

   Conference participant C asks the media server M to record a session.
   If the session description contains any alternatives, the server
   records them all.

```
    C->M: SESSION meeting RTSP/1.0 89
          Content-type: application/sdp

          v=0
          s=Mbone Audio
          i=Discussion of Mbone Engineering Issues

    M->C: 415 89 Unsupported Media Type
          Accept: application/sdf

    C->M: SESSION meeting RTSP/1.0 90
          Content-type: application/sdf

    M->C: 200 90 OK

    C->M: RECORD meeting
          Range: clock 19961110T1925-19961110T2015
```

Access Authentication

   Besides limiting access, access authentication is also needed to
   avoid denial-of-service attacks.

[8](#) Security Considerations

   The protocol offers the opportunity for a remote-control denial-of-
   service attack. The attacker, using a forged source IP address, can
   ask for a stream to be played back to that forged IP address. This
   can be prevented by a challenge-response authentication. If the goal
   is simply to prevent this denial-of-service attack, a default, widely
   known key can be used.

   If the client retrieves a session description, the server hand out an
   encrypted version of the client's IP address to the client during the
   initial retrieval of the session description.

A Session Description

   A session description must be able to identify sessions and
   individual media streams. The per-media identifier is created by the
   entity creating the session description and is opaque to anyone else.
   It may contain any 8-bit value except CR and LF.

B Notes on RTSP

         o The STREAM_HEADER functionality has been subsumed by the
           session description.

         o SEND_REPORT is not really needed. Should define an RTCP
           request with a random response interval.

         o Error reports are sent automatically. If server wants to
           terminate connection, it sends a BYE.

         o Resending (UDP_RESEND) should be handled by RTCP since it is
           always media-specific and RTCP can be readily flow-controlled
           to avoid congestion collapse.

         o Is STOP really needed? What's the difference between STOP and
           PAUSE? Resources (which?) cannot be released since there may be
           a PLAY command immediately. Bearing on resource reservation?
