# Remote Direct Memory Access Transport for Remote Procedure Call, Version One

draft-ietf-nfsv4-rfc5666bis-08

## Abstract

This document specifies a protocol for conveying Remote Procedure Call (RPC) messages on physical transports capable of Remote Direct Memory Access (RDMA). It requires no revision to application RPC protocols or the RPC protocol itself. This document obsoletes RFC 5666.

## Status of This Memo

This Internet-Draft is submitted in full conformance with the provisions of BCP 78 and BCP 79.

Internet-Drafts are working documents of the Internet Engineering Task Force (IETF). Note that other groups may also distribute working documents as Internet-Drafts. The list of current Internet-Drafts is at http://datatracker.ietf.org/drafts/current/.

Internet-Drafts are draft documents valid for a maximum of six months and may be updated, replaced, or obsoleted by other documents at any time. It is inappropriate to use Internet-Drafts as reference material or to cite them other than as "work in progress."

This Internet-Draft will expire on May 25, 2017.

## 1. Introduction

This document obsoletes RFC 5666. However, the protocol specified by this document is based on existing interoperating implementations of the RPC-over-RDMA Version One protocol.

The new specification clarifies text that is subject to multiple interpretations, and removes support for unimplemented RPC-over-RDMA Version One protocol elements. It clarifies the role of Upper Layer Bindings and describes what they are to contain.

In addition, this document describes current practice using RPCSEC_GSS [I-D.ietf-nfsv4-rpcsec-gssv3] on RDMA transports.

### 1.1. Requirements Language

The key words "MUST", "MUST NOT", "REQUIRED", "SHALL", "SHALL NOT", "SHOULD", "SHOULD NOT", "RECOMMENDED", "MAY", and "OPTIONAL" in this document are to be interpreted as described in [RFC2119].

### 1.2. Remote Procedure Calls On RDMA Transports

Remote Direct Memory Access (RDMA) [RFC5040] [RFC5041] [IB] is a technique for moving data efficiently between end nodes. By directing data into destination buffers as it is sent on a network, and placing it via direct memory access by hardware, the benefits of faster transfers and reduced host overhead are obtained.

Open Network Computing Remote Procedure Call (ONC RPC, or simply, RPC) [RFC5531] is a remote procedure call protocol that runs over a variety of transports. Most RPC implementations today use UDP [RFC0768] or TCP [RFC0793]. On UDP, RPC messages are encapsulated inside datagrams, while on a TCP byte stream, RPC messages are delineated by a record marking protocol. An RDMA transport also conveys RPC messages in a specific fashion that must be fully described if RPC implementations are to interoperate.

RDMA transports present semantics different from either UDP or TCP. They retain message delineations like UDP, but provide reliable and sequenced data transfer like TCP. They also provide an offloaded bulk transfer service not provided by UDP or TCP. RDMA transports are therefore appropriately viewed as a new transport type by RPC.

In this context, the Network File System (NFS) protocols as described in [RFC1094], [RFC1813], [RFC7530], [RFC5661], and future NFSv4 minor verions are all obvious beneficiaries of RDMA transports. A complete problem statement is presented in [RFC5532]. Many other RPC-based protocols can also benefit.

Although the RDMA transport described herein can provide relatively transparent support for any RPC application, this document also describes mechanisms that can optimize data transfer even further, given more active participation by RPC applications.

## 2. Changes Since RFC 5666

### 2.1. Changes To The Specification

The following alterations have been made to the RPC-over-RDMA Version One specification. The section numbers below refer to [RFC5666].

- Section 2 has been expanded to introduce and explain key RPC, XDR, and RDMA terminology. These terms are now used consistently throughout the specification.

- Section 3 has been re-organized and split into sub-sections to help readers locate specific requirements and definitions.

- Sections 4 and 5 have been combined to improve the organization of this information.

- The specification of the optional Connection Configuration Protocol has been removed from the specification.

- A section consolidating requirements for Upper Layer Bindings has been added.

- An XDR extraction mechanism is provided, along with full copyright, matching the approach used in [RFC5662].

- The "Security Considerations" section has been expanded to include a discussion of how RPC-over-RDMA security depends on features of the underlying RDMA transport.

- A subsection describing the use of RPCSEC_GSS with RPC-over-RDMA Version One has been added.

### 2.2. Changes To The Protocol

Although the protocol described herein interoperates with existing implementations of [RFC5666], the following changes have been made relative to the protocol described in that document:

- Support for the Read-Read transfer model has been removed. Read-Read is a slower transfer model than Read-Write. As a result, implementers have chosen not to support it. Removal simplifies

explanatory text, and support for the RDMA_DONE procedure is no longer necessary.

- The specification of RDMA_MSGP in [RFC5666] is not adequate, although some incomplete implementations exist. Even if an adequate specification were provided and an implementation was produced, benefit for protocols such as NFSv4.0 [RFC7530] is doubtful. Therefore the RDMA_MSGP message type is no longer supported.

- Technical issues with regard to handling RPC-over-RDMA header errors have been corrected.

- Specific requirements related to implicit XDR round-up and complex XDR data types have been added.

- Explicit guidance is provided related to sizing Write chunks, managing multiple chunks in the Write list, and handling unused Write chunks.

- Clear guidance about Send and Receive buffer sizes has been introduced. This enables better decisions about when a Reply chunk must be provided.

The protocol version number has not been changed because the protocol specified in this document fully interoperates with implementations of the RPC-over-RDMA Version One protocol specified in [RFC5666].

## 3. Terminology

### 3.1. Remote Procedure Calls

This section highlights key elements of the Remote Procedure Call [RFC5531] and External Data Representation [RFC4506] protocols, upon which RPC-over-RDMA Version One is constructed. Strong grounding with these protocols is recommended before reading this document.

#### 3.1.1. Upper Layer Protocols

Remote Procedure Calls are an abstraction used to implement the operations of an "Upper Layer Protocol," or ULP. The term Upper Layer Protocol refers to an RPC Program and Version tuple, which is a versioned set of procedure calls that comprise a single well-defined API. One example of an Upper Layer Protocol is the Network File System Version 4.0 [RFC7530].

### 3.1.2. Requesters And Responders

Like a local procedure call, every Remote Procedure Call (RPC) has a set of "arguments" and a set of "results". A calling context is not allowed to proceed until the procedure's results are available to it. Unlike a local procedure call, the called procedure is executed remotely rather than in the local application's context.

The RPC protocol as described in [RFC5531] is fundamentally a message-passing protocol between one server and one or more clients. ONC RPC transactions are made up of two types of messages:

CALL Message
: A CALL message, or "Call", requests that work be done. A Call is designated by the value zero (0) in the message's msg_type field. An arbitrary unique value is placed in the message's xid field in order to match this CALL message to a corresponding REPLY message.

REPLY Message
: A REPLY message, or "Reply", reports the results of work requested by a Call. A Reply is designated by the value one (1) in the message's msg_type field. The value contained in the message's xid field is copied from the Call whose results are being reported.

The RPC client endpoint acts as a "requester". It serializes an RPC Call's arguments and conveys them to a server endpoint via an RPC Call message. This message contains an RPC protocol header, a header describing the requested upper layer operation, and all arguments.

The RPC server endpoint acts as a "responder". It deserializes Call arguments, and processes the requested operation. It then serializes the operation's results into another byte stream. This byte stream is conveyed back to the requester via an RPC Reply message. This message contains an RPC protocol header, a header describing the upper layer reply, and all results.

The requester deserializes the results and allows the original caller to proceed. At this point the RPC transaction designated by the xid in the Call message is complete, and the xid is retired.

In summary, CALL messages are sent by requesters to responders to initiate an RPC transaction. REPLY messages are sent by responders to requesters to complete the processing on an RPC transaction.

### 3.1.3. RPC Transports

The role of an "RPC transport" is to mediate the exchange of RPC messages between requesters and responders. An RPC transport bridges the gap between the RPC message abstraction and the native operations of a particular network transport.

RPC-over-RDMA is a connection-oriented RPC transport. When a connection-oriented transport is used, clients initiate transport connections, while servers wait passively for incoming connection requests.

### 3.1.4. External Data Representation

One cannot assume that all requesters and responders internally represent data objects the same way. RPC uses eXternal Data Representation, or XDR, to translate data types and serialize arguments and results [RFC4506].

The XDR protocol encodes data independent of the endianness or size of host-native data types, allowing unambiguous decoding of data on the receiving end. RPC Programs are specified by writing an XDR definition of their procedures, argument data types, and result data types.

XDR assumes that the number of bits in a byte (octet) and their order are the same on both endpoints and on the physical network. The smallest indivisible unit of XDR encoding is a group of four octets in little-endian order. XDR also flattens lists, arrays, and other complex data types so they can be conveyed as a stream of bytes.

A serialized stream of bytes that is the result of XDR encoding is referred to as an "XDR stream." A sending endpoint encodes native data into an XDR stream and then transmits that stream to a receiver. A receiving endpoint decodes incoming XDR byte streams into its native data representation format.

#### 3.1.4.1. XDR Opaque Data

Sometimes a data item must be transferred as-is, without encoding or decoding. The contents of such a data item are referred to as "opaque data." XDR encoding places the content of opaque data items directly into an XDR stream without altering it in any way. Upper Layer Protocols or applications perform any needed data translation in this case. Examples of opaque data items include the content of files, or generic byte strings.

#### 3.1.4.2. XDR Round-up

The number of octets in a variable-size opaque data item precedes that item in an XDR stream. If the size of an encoded data item is not a multiple of four octets, octets containing zero are added to the end of the item as it is encoded so that the next encoded data item starts on a four-octet boundary. The encoded size of the item is not changed by the addition of the extra octets, and the zero bytes are not exposed to the Upper Layer.

This technique is referred to as "XDR round-up," and the extra octets are referred to as "XDR padding".

## 3.2. Remote Direct Memory Access

RPC requesters and responders can be made more efficient if large RPC messages are transferred by a third party such as intelligent network interface hardware (data movement offload), and placed in the receiver's memory so that no additional adjustment of data alignment has to be made (direct data placement). Remote Direct Memory Access transports enable both optimizations.

### 3.2.1. Direct Data Placement

Typically, RPC implementations copy the contents of RPC messages into a buffer before being sent. An efficient RPC implementation sends bulk data without copying it into a separate send buffer first.

However, socket-based RPC implementations are often unable to receive data directly into its final place in memory. Receivers often need to copy incoming data to finish an RPC operation; sometimes, only to adjust data alignment.

In this document, "RDMA" refers to the physical mechanism an RDMA transport utilizes when moving data. Although this may not be efficient, before an RDMA transfer a sender may copy data into an intermediate buffer before an RDMA transfer. After an RDMA transfer, a receiver may copy that data again to its final destination.

This document uses the term "direct data placement" (or DDP) to refer specifically to an optimized data transfer where it is unnecessary for a receiving host's CPU to copy transferred data to another location after it has been received. Not all RDMA-based data transfer qualifies as Direct Data Placement, and DDP can be achieved using non-RDMA mechanisms.

### 3.2.2. RDMA Transport Requirements

The RPC-over-RDMA Version One protocol assumes the physical transport provides the following abstract operations. A more complete discussion of these operations is found in [RFC5040].

Registered Memory

Registered memory is a segment of memory that is assigned a steering tag that temporarily permits access by the RDMA provider to perform data transfer operations. The RPC-over-RDMA Version One protocol assumes that each segment of registered memory MUST be identified with a steering tag of no more than 32 bits and memory addresses of up to 64 bits in length.

RDMA Send

The RDMA provider supports an RDMA Send operation, with completion signaled on the receiving peer after data has been placed in a pre-posted memory segment. Sends complete at the receiver in the order they were issued at the sender. The amount of data transferred by an RDMA Send operation is limited by the size of the remote pre-posted memory segment.

RDMA Receive

The RDMA provider supports an RDMA Receive operation to receive data conveyed by incoming RDMA Send operations. To reduce the amount of memory that must remain pinned awaiting incoming Sends, the amount of pre-posted memory is limited. Flow-control to prevent overrunning receiver resources is provided by the RDMA consumer (in this case, the RPC-over-RDMA Version One protocol).

RDMA Write

The RDMA provider supports an RDMA Write operation to directly place data in remote memory. The local host initiates an RDMA Write, and completion is signaled there. No completion is signaled on the remote. The local host provides a steering tag, memory address, and length of the remote's memory segment.

RDMA Writes are not necessarily ordered with respect to one another, but are ordered with respect to RDMA Sends. A subsequent RDMA Send completion obtained at the write initiator guarantees that prior RDMA Write data has been successfully placed in the remote peer's memory.

RDMA Read

The RDMA provider supports an RDMA Read operation to directly place peer source data in the read initiator's memory. The local host initiates an RDMA Read, and completion is signaled there; no completion is signaled on the remote. The local host provides

steering tags, memory addresses, and a length for the remote source and local destination memory segments.

The remote peer receives no notification of RDMA Read completion. The local host signals completion as part of a subsequent RDMA Send message so that the remote peer can release steering tags and subsequently free associated source memory segments.

The RPC-over-RDMA Version One protocol is designed to be carried over RDMA transports that support the above abstract operations. This protocol conveys to the RPC peer information sufficient for that RPC peer to direct an RDMA layer to perform transfers containing RPC data and to communicate their result(s). For example, it is readily carried over RDMA transports such as Internet Wide Area RDMA Protocol (iWARP) [RFC5040] [RFC5041].

## 4. RPC-Over-RDMA Protocol Framework

### 4.1. Transfer Models

A "transfer model" designates which endpoint is responsible for performing RDMA Read and Write operations. To enable these operations, the peer endpoint first exposes segments of its memory to the endpoint performing the RDMA Read and Write operations.

Read-Read
: Requesters expose their memory to the responder, and the responder exposes its memory to requesters. The responder employs RDMA Read operations to pull RPC arguments or whole RPC calls from the requester. Requesters employ RDMA Read operations to pull RPC results or whole RPC relies from the responder.

Write-Write
: Requesters expose their memory to the responder, and the responder exposes its memory to requesters. Requesters employ RDMA Write operations to push RPC arguments or whole RPC calls to the responder. The responder employs RDMA Write operations to push RPC results or whole RPC relies to the requester.

Read-Write
: Requesters expose their memory to the responder, but the responder does not expose its memory. The responder employs RDMA Read operations to pull RPC arguments or whole RPC calls from the requester. The responder employs RDMA Write operations to push RPC results or whole RPC relies to the requester.

Write-Read

The responder exposes its memory to requesters, but requesters do not expose their memory. Requesters employ RDMA Write operations to push RPC arguments or whole RPC calls to the responder. Requesters employ RDMA Read operations to pull RPC results or whole RPC relies from the responder.

[RFC5666] specifies the use of both the Read-Read and the Read-Write Transfer Model. All current RPC-over-RDMA Version One implementations use only the Read-Write Transfer Model. Therefore the use of the Read-Read Transfer Model within RPC-over-RDMA Version One implementations is no longer supported. Transfer Models other than the Read-Write model may be used in future versions of RPC-over-RDMA.

## 4.2. Message Framing

On an RPC-over-RDMA transport, each RPC message is encapsulated by an RPC-over-RDMA message. An RPC-over-RDMA message consists of two XDR streams.

RPC Payload Stream
: The "Payload stream" contains the encapsulated RPC message being transferred by this RPC-over-RDMA message. This stream always begins with the XID field of the encapsulated RPC message.

Transport Stream
: The "Transport stream" contains a header that describes and controls the transfer of the Payload stream in this RPC-over-RDMA message. This header is analogous to the record marking used for RPC over TCP but is more extensive, since RDMA transports support several modes of data transfer.

In its simplest form, an RPC-over-RDMA message consists of a Transport stream followed immediately by a Payload stream conveyed together in a single RDMA Send. To transmit large RPC messages, a combination of one RDMA Send operation and one or more RDMA Read or Write operations is employed.

RPC-over-RDMA framing replaces all other RPC framing (such as TCP record marking) when used atop an RPC-over-RDMA association, even when the underlying RDMA protocol may itself be layered atop a transport with a defined RPC framing (such as TCP).

It is however possible for RPC-over-RDMA to be dynamically enabled in the course of negotiating the use of RDMA via an Upper Layer Protocol exchange. Because RPC framing delimits an entire RPC request or reply, the resulting shift in framing must occur between distinct RPC messages, and in concert with the underlying transport.

### 4.3. Managing Receiver Resources

It is critical to provide RDMA Send flow control for an RDMA connection. If any pre-posted receive buffer on the connection is not large enough to accept an incoming RDMA Send, the RDMA Send operation can fail. If a pre-posted receive buffer is not available to accept an incoming RDMA Send, the RDMA Send operation can fail. Repeated occurrences of such errors can be fatal to the connection. This is different than conventional TCP/IP networking, in which buffers are allocated dynamically as messages are received.

The longevity of an RDMA connection requires that sending endpoints respect the resource limits of peer receivers. To ensure messages can be sent and received reliably, there are two operational parameters for each connection.

#### 4.3.1. RPC-over-RDMA Credits

Flow control for RDMA Send operations directed to the responder is implemented as a simple request/grant protocol in the RPC-over-RDMA header associated with each RPC message.

An RPC-over-RDMA Version One credit is the capability to handle one RPC-over-RDMA transaction. Each RPC-over-RDMA message sent from requester to responder requests a number of credits from the responder. Each RPC-over-RDMA message sent from responder to requester informs the requester how many credits the responder has granted. The requested and granted values are carried in each RPC-over-RDMA message's rdma_credit field (see Section 5.2.3).

Practically speaking, the critical value is the granted value. A requester MUST NOT send unacknowledged requests in excess of the responder's granted credit limit. If the granted value is exceeded, the RDMA layer may signal an error, possibly terminating the connection. The granted value MUST NOT be zero, since such a value would result in deadlock.

RPC calls complete in any order, but the current granted credit limit at the responder is known to the requester from RDMA Send ordering properties. The number of allowed new requests the requester may send is then the lower of the current requested and granted credit values, minus the number of requests in flight. Advertised credit values are not altered when individual RPCs are started or completed.

The requested and granted credit values MAY be adjusted to match the needs or policies in effect on either peer. For instance, a responder may reduce the granted credit value to accommodate the available resources in a Shared Receive Queue. The responder MUST

ensure that an increase in receive resources is effected before the next reply message is sent.

A requester MUST maintain enough receive resources to accommodate expected replies. Responders have to be prepared for there to be no receive resources available on requesters with no pending RPC transactions.

Certain RDMA implementations may impose additional flow control restrictions, such as limits on RDMA Read operations in progress at the responder. Accommodation of such restrictions is considered the responsibility of each RPC-over-RDMA Version One implementation.

### 4.3.2. Inline Threshold

An "inline threshold" value is the largest message size (in octets) that can be conveyed in one direction between peer implementations using RDMA Send and Receive. The inline threshold value is the minimum of how large a message the sender can post via an RDMA Send operation, and how large a message the receiver can accept via an RDMA Receive operation. Each connection has two inline threshold values: one for messages flowing from requester-to-responder (referred to as the "call inline threshold"), and one for messages flowing from responder-to-requester (referred to as the "reply inline threshold").

Unlike credit limits, inline threshold values are not advertised to peers via the RPC-over-RDMA Version One protocol, and there is no provision for inline threshold values to change during the lifetime of an RPC-over-RDMA Version One connection.

### 4.3.3. Initial Connection State

When a connection is first established, peers might not know how many receive resources the other has, nor how large the other peer's inline thresholds are.

As a basis for an initial exchange of RPC requests, each RPC-over-RDMA Version One connection provides the ability to exchange at least one RPC message at a time, whose Call and Reply messages are no more 1024 bytes in size. A responder MAY exceed this basic level of configuration, but a requester MUST NOT assume more than one credit is available, and MUST receive a valid reply from the responder carrying the actual number of available credits, prior to sending its next request.

Receiver implementations MUST support inline thresholds of 1024 bytes, but MAY support larger inline thresholds values. A mechanism

for discovering a peer's inline thresholds before a connection is established may be used to optimize the use of RDMA Send and Receive operations. In the absense of such a mechanism, senders and receives MUST assume the inline thresholds are 1024 bytes.

## 4.4. XDR Encoding With Chunks

When a direct data placement capability is available, it can be determined during XDR encoding that the transport can efficiently place the contents of one or more XDR data items directly into the receiver's memory, separately from the transfer of other parts of the containing XDR stream.

### 4.4.1. Reducing An XDR Stream

RPC-over-RDMA Version One provides a mechanism for moving part of an RPC message via a data transfer separate from an RDMA Send/Receive. The sender removes one or more XDR data items from the Payload stream. They are conveyed via one or more RDMA Read or Write operations. As the receiver decodes an incoming message, it skips over directly placed data items.

The piece of memory containing the portion of the data stream that is split out and placed directly is referred to as a "chunk". In some contexts, data in the RPC-over-RDMA header that describes such pieces of memory is also referred to as a "chunk".

A Payload stream after chunks have been removed is referred to as a "reduced" Payload stream. Likewise, a data item that has been removed from a Payload stream to be transferred separately is referred to as a "reduced" data item.

### 4.4.2. DDP-Eligibility

Only an XDR data item that might benefit from Direct Data Placement may be reduced. The eligibility of particular XDR data items to be reduced is independent of RPC-over-RDMA, and thus is not specified by this document.

To maintain interoperability on an RPC-over-RDMA transport, a determination must be made of which XDR data items in each Upper Layer Protocol are allowed to use Direct Data Placement. Therefore an additional specification is needed that describes how an Upper Layer Protocol enables Direct Data Placement. The set of requirements for an Upper Layer Protocol to use an RPC-over-RDMA transport is known as an "Upper Layer Binding specification," or ULB.

An Upper Layer Binding specification states which specific individual XDR data items in an Upper Layer Protocol MAY be transferred via Direct Data Placement. This document will refer to XDR data items that are permitted to be reduced as "DDP-eligible". All other XDR data items MUST NOT be reduced. RPC-over-RDMA Version One uses RDMA Read and Write operations to transfer DDP-eligible data that has been reduced.

Detailed requirements for Upper Layer Bindings are discussed in full in Section 7.

### 4.4.3. RDMA Segments

When encoding a Payload stream that contains a DDP-eligible data item, a sender may choose to reduce that data item. When it chooses to do so, the sender does not place the item into the Payload stream. Instead, the sender records in the RPC-over-RDMA header the location and size of the memory region containing that data item.

The requester provides location information for DDP-eligible data items in both RPC Calls and Replies. The responder uses this information to initiate RDMA Read and Write operations to retrieve or update the specified region of the requester's memory.

An "RDMA segment", or a "plain segment", is an RPC-over-RDMA header data object that contains the precise co-ordinates of a contiguous memory region that is to be conveyed via one or more RDMA Read or RDMA Write operations.

Handle
: Steering tag (STag) or handle obtained when the segment's memory is registered for RDMA. Also known as an R_key, this value is generated by registering this memory with the RDMA provider.

Length
: The length of the memory segment, in octets.

Offset
: The offset or beginning memory address of the segment.

See [RFC5040] for further discussion of the meaning of these fields.

### 4.4.4. Chunks

In RPC-over-RDMA Version One, a "chunk" refers to a portion of the Payload stream that is moved via RDMA Read or Write operations. Chunk data is removed from the sender's Payload stream, transferred

by separate RDMA operations, and then re-inserted into the receiver's Payload stream.

Each chunk consists of one or more RDMA segments. Each segment represents a single contiguous piece of that chunk. A requester MAY divide a chunk into segments using any boundaries that are convenient.

Except in special cases, a chunk contains exactly one XDR data item. This makes it straightforward to remove chunks from an XDR stream without affecting XDR alignment.

Many RPC-over-RDMA messages have no associated chunks. In this case, all three chunk lists are marked empty.

#### 4.4.4.1. Counted Arrays

If a chunk contains a counted array data type, the count of array elements MUST remain in the Payload stream, while the array elements MUST be moved to the chunk. For example, when encoding an opaque byte array as a chunk, the count of bytes stays in the Payload stream, while the bytes in the array are removed from the Payload stream and transferred within the chunk.

Any byte count left in the Payload stream MUST match the sum of the lengths of the segments making up the chunk. If they do not agree, an RPC protocol encoding error results.

Individual array elements appear in a chunk in their entirety. For example, when encoding an array of arrays as a chunk, the count of items in the enclosing array stays in the Payload stream, but each enclosed array, including its item count, is transferred as part of the chunk.

#### 4.4.4.2. Optional-data

If a chunk contains an optional-data data type, the "is present" field MUST remain in the Payload stream, while the data, if present, MUST be moved to the chunk.

#### 4.4.4.3. XDR Unions

A union data type should never be made DDP-eligible, but one or more of its arms may be DDP-eligible.

### 4.4.5. Read Chunks

A "Read chunk" represents an XDR data item that is to be pulled from the requester to the responder using RDMA Read operations.

A Read chunk is a list of one or more RDMA read segments. Each RDMA read segment consists of a Position field followed by a plain segment. See Section 5.1.2 for details.

Position
: The byte offset in the unreduced Payload stream where the receiver re-inserts the data item conveyed in a chunk. The Position value MUST be computed from the beginning of the unreduced Payload stream, which begins at Position zero. All RDMA read segments belonging to the same Read chunk have the same value in their Position field.

While constructing an RPC-over-RDMA Call message, a requester registers memory segments that contain data to be transferred via RDMA Read operations. It advertises the co-ordinates of these segments in the RPC-over-RDMA header of the RPC Call.

After receiving an RPC Call sent via an RDMA Send operation, a responder transfers the chunk data from the requester using RDMA Read operations. The responder reconstructs the transferred chunk data by concatenating the contents of each segment, in list order, into the received Payload stream at the Position value recorded in the segment.

Put another way, the responder inserts the first segment in a Read chunk into the Payload stream at the byte offset indicated by its Position field. Segments whose Position field value match this offset are concatenated afterwards, until there are no more segments at that Position value. The next XDR data item in the Payload stream follows.

#### 4.4.5.1. Read Chunk Round-up

XDR requires each encoded data item to start on four-byte alignment. When an odd-length data item is encoded, its length is encoded literally, while the data is padded so the next data item in the XDR stream can start on a four-byte boundary. Receivers ignore the content of the pad bytes.

After an XDR data item has been reduced, all data items remaining in the Payload stream must continue to adhere to these padding requirements. Thus when an XDR data item is moved from the Payload

stream into a Read chunk, the requester MUST remove XDR padding for that data item from the Payload stream as well.

The length of a Read chunk is the sum of the lengths of the read segments that comprise it. If this sum is not a multiple of four, the requester MAY choose to send a Read chunk without any XDR padding. If the requester provides no actual round-up in a Read chunk, the responder MUST be prepared to provide appropriate round-up in the reconstructed call XDR stream

The Position field in a read segment indicates where the containing Read chunk starts in the Payload stream. The value in this field MUST be a multiple of four. Moreover, all segments in the same Read chunk share the same Position value, even if one or more of the segments have a non-four-byte aligned length.

#### 4.4.5.2. Decoding Read Chunks

While decoding a received Payload stream, whenever the XDR offset in the Payload stream matches that of a Read chunk, the responder initiates an RDMA Read to pull the chunk's data content into registered local memory.

The responder acknowledges its completion of use of Read chunk source buffers when it sends an RPC Reply to the requester. The requester may then release Read chunks advertised in the request.

### 4.4.6. Write Chunks

A "Write chunk" represents an XDR data item that is to be pushed from a responder to a requester using RDMA Write operations.

A Write chunk is an array of one or more plain RDMA segments. Write chunks are provided by a requester long before the responder has prepared the reply Payload stream. In most cases, the byte offset of a particular XDR data item in the reply is not predictable at the time a request is issued. Therefore RDMA segments in a Write chunk do not have a Position field.

While constructing an RPC Call message, a requester also prepares memory regions to catch DDP-eligible reply data items. A requester does not know the actual length of the result data item to be returned, thus it MUST register a Write chunk long enough to accommodate the maximum possible size of the returned data item.

The responder fills the segments contiguously in array order until the result data item has been completely written into the Write chunk. The responder copies the consumed Write chunk segments into

the Reply's RPC-over-RDMA header. As it does so, the responder updates the segment length fields to reflect the actual amount of data that is being returned in each segment, and updates the Write chunk's segment count to reflect how many segments were consumed. Unconsumed segments are omitted in the returned Write chunk.

The responder then sends the RPC Reply via an RDMA Send operation. After receiving the RPC Reply, the requester reconstructs the transferred data by concatenating the contents of each segment, in array order, into RPC Reply XDR stream.

#### 4.4.6.1. Write Chunk Round-up

XDR requires each encoded data item to start on four-byte alignment. When an odd-length data item is encoded, its length is encoded literally, while the data is padded so the next data item in the XDR stream can start on a four-byte boundary. Receivers ignore the content of the pad bytes.

After a data item is reduced, data items remaining in the Payload stream must continue to adhere to these padding requirements. Thus when an XDR data item is moved from a reply Payload stream into a Write chunk, the responder MUST remove XDR padding for that data item from the reply Payload stream as well.

A requester SHOULD NOT provide extra length in a Write chunk to accommodate XDR pad bytes. A responder MUST NOT write XDR pad bytes for a Write chunk.

#### 4.4.6.2. Unused Write Chunks

There are occasions when a requester provides a Write chunk but the responder is not able to use it.

For example, an Upper Layer Protocol may define a union result where some arms of the union contain a DDP-eligible data item while other arms do not. The responder is REQUIRED to use requester-provided Write chunks in this case, but if the responder returns a result that uses an arm of the union that has no DDP-eligible data item, the Write chunk remains unconsumed.

If there is a subsequent DDP-eligible data item, it MUST be placed in that unconsumed Write chunk. The requester MUST provision each Write chunk so it can be filled with the largest DDP-eligible data item that can be placed in it.

However, if this is the last or only Write chunk available and it remains unconsumed, The responder MUST set the Write chunk segment count to zero, returning no segments in the Write chunk.

Unused write chunks, or unused bytes in write chunk segments, are not returned as results. Their memory is returned to the Upper Layer as part of RPC completion. However, the RPC layer MUST NOT assume that the buffers have not been modified.

In other words, even if a responder indicates that a Write chunk is not consumed (by setting all of the segment lengths in the chunk to zero), the responder may have written some data into the segments before deciding not to return that data item. For example, a problem reading local storage might occur while an NFS server is filling Write chunks. This would interrupt the stream of RDMA Write operations that sends data back to the NFS client, but at that point the NFS server needs to return an NFS error that reflects that the Upper Layer NFS request has failed.

When there is a DDP-eligible result data item, and the requester prefers the data item returned inline, the requester provides a Write chunk for that item where either the segment count is zero, or the length of each of the chunk's segments is zero. The responder MUST return the corresponding data item inline.

## 4.5. Message Size

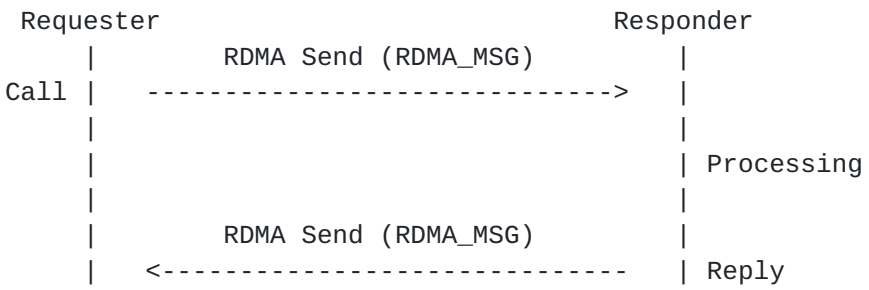
A receiver of RDMA Send operations is required by RDMA to have previously posted one or more adequately sized buffers. Memory savings are achieved on both requesters and responders by posting small Receive buffers. However, not all RPC messages are small.

### 4.5.1. Short Messages

RPC messages are frequently smaller than typical inline thresholds. For example, the NFS version 3 GETATTR operation is only 56 bytes: 20 bytes of RPC header, plus a 32-byte file handle argument and 4 bytes for its length. The reply to this common request is about 100 bytes.

Since all RPC messages conveyed via RPC-over-RDMA require an RDMA Send operation, the most efficient way to send an RPC message that is smaller than the inline threshold is to append the Payload stream directly to the Transport stream. An RPC-over-RDMA header with a small RPC Call or Reply message immediately following is transferred using a single RDMA Send operation. No RDMA Read or Write operations are needed.

An RPC-over-RDMA transaction using Short Messages:

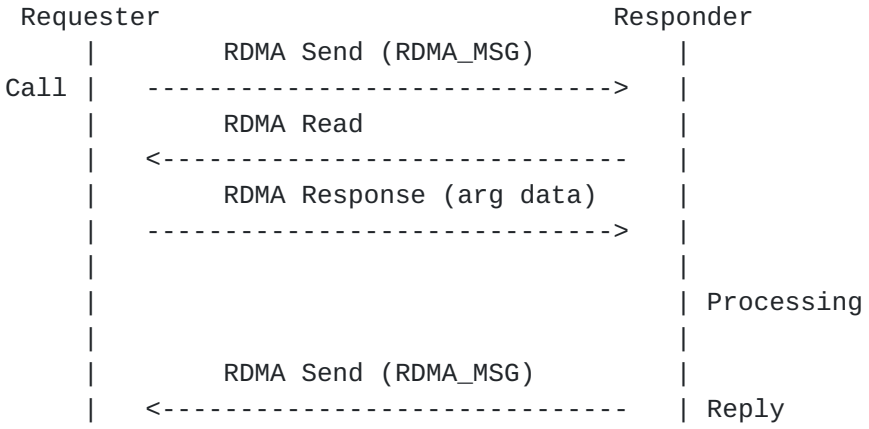


### 4.5.2. Chunked Messages

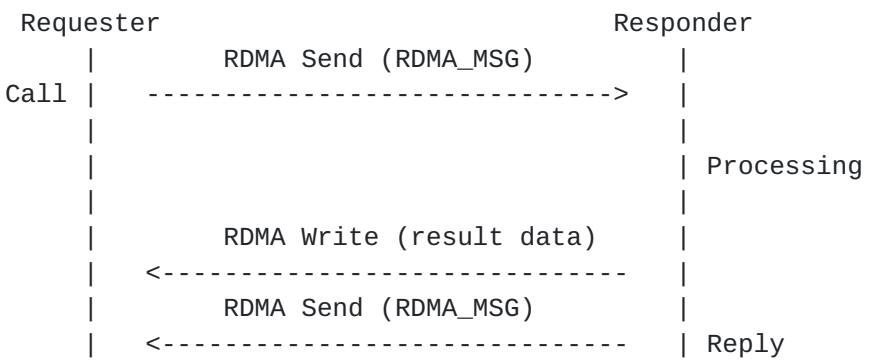
If DDP-eligible data items are present in a Payload stream, a sender MAY reduce some or all of these items by removing them from the Payload stream. The sender uses RDMA Read or Write operations to transfer the reduced data items. The Transport stream with the reduced Payload stream immediately following is then transferred using a single RDMA Send operation

After receiving the Transport and Payload streams of a Chunked RPC-over-RDMA Call message, the responder uses RDMA Read operations to move reduced data items in Read chunks. Before sending the Transport and Payload streams of a Chunked RPC-over-RDMA Reply message, the responder uses RDMA Write operations to move reduced data items in Write and Reply chunks.

An RPC-over-RDMA transaction with a Read chunk:



An RPC-over-RDMA transaction with a Write chunk:



### 4.5.3. Long Messages

When a Payload stream is larger than the receiver's inline threshold, the Payload stream is reduced by removing DDP-eligible data items and placing them in chunks to be moved separately. If there are no DDP-eligible data items in the Payload stream, or the Payload stream is still too large after it has been reduced, the RDMA transport MUST use RDMA Read or Write operations to convey the Payload stream itself. This mechanism is referred to as a "Long Message."

To transmit a Long Message, the sender conveys only the Transport stream with an RDMA Send operation. The Payload stream is not included in the Send buffer in this instance. Instead, the requester provides chunks that the responder uses to move the Payload stream.

Long RPC Call
: To send a Long RPC-over-RDMA Call message, the requester provides a special Read chunk that contains the RPC Call's Payload stream. Every segment in this Read chunk MUST contain zero in its Position field. Thus this chunk is known as a "Position Zero Read chunk."

Long RPC Reply
: To send a Long RPC-over-RDMA Reply message, the requester provides a single special Write chunk in advance, known as the "Reply chunk", that will contain the RPC Reply's Payload stream. The requester sizes the Reply chunk to accommodate the maximum expected reply size for that Upper Layer operation.

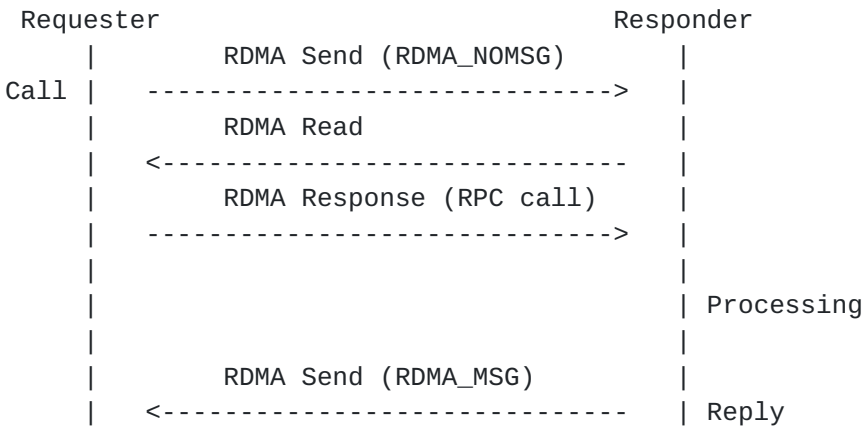
Though the purpose of a Long Message is to handle large RPC messages, requesters MAY use a Long Message at any time to convey an RPC Call.

A responder chooses which form of reply to use based on the chunks provided by the requester. If Write chunks were provided and the responder has a DDP-eligible result, it first reduces the reply Payload stream. If a Reply chunk was provided and the reduced

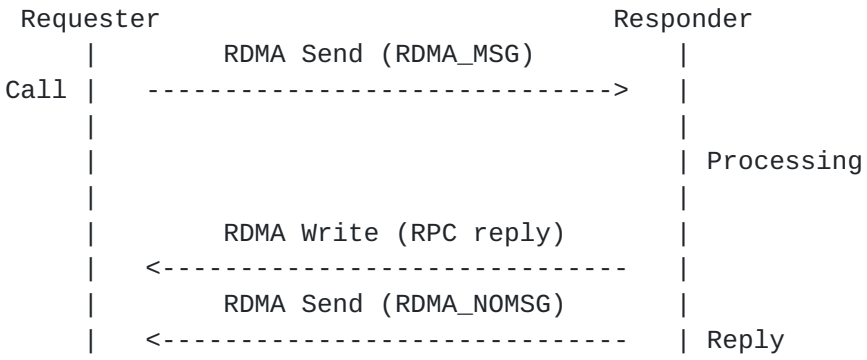
Payload stream is larger than the reply inline threshold, the responder MUST use the requester-provided Reply chunk for the reply.

Because these special chunks contain a whole RPC message, XDR data items appear in these special chunks without regard to their DDP-eligibility.

An RPC-over-RDMA transaction using a Long Call:



An RPC-over-RDMA transaction using a Long Reply:



## 5. RPC-Over-RDMA In Operation

Every RPC-over-RDMA Version One message has a header that includes a copy of the message's transaction ID, data for managing RDMA flow control credits, and lists of RDMA segments used for RDMA Read and Write operations. All RPC-over-RDMA header content is contained in the Transport stream, and thus MUST be XDR encoded.

RPC message layout is unchanged from that described in [RFC5531] except for the possible reduction of data items that are moved by RDMA Read or Write operations.

The RPC-over-RDMA protocol passes RPC messages without regard to their type (CALL or REPLY). Apart from restrictions imposed by upper-layer bindings, each endpoint of a connection MAY send RDMA_MSG or RDMA_NOMSG message header types at any time (subject to credit limits).

## 5.1. XDR Protocol Definition

This section contains a description of the core features of the RPC-over-RDMA Version One protocol, expressed in the XDR language [RFC4506].

This description is provided in a way that makes it simple to extract into ready-to-compile form. The reader can apply the following shell script to this document to produce a machine-readable XDR description of the RPC-over-RDMA Version One protocol.

```
<CODE BEGINS>

#!/bin/sh
grep '^ *///' | sed 's?^ /// ??' | sed 's?^ *///$??'

<CODE ENDS>
```

That is, if the above script is stored in a file called "extract.sh" and this document is in a file called "spec.txt" then the reader can do the following to extract an XDR description file:

```
<CODE BEGINS>

sh extract.sh < spec.txt > rpcrdma_corev1.x

<CODE ENDS>
```

### 5.1.1. Code Component License

Code components extracted from this document must include the following license text. When the extracted XDR code is combined with other complementary XDR code which itself has an identical license, only a single copy of the license text need be preserved.

<CODE BEGINS>

```

///    rdma_body rdma_body;
/// };
```

<CODE ENDS>

## 5.2. Fixed Header Fields

The RPC-over-RDMA header begins with four fixed 32-bit fields that control the RDMA interaction.

The first three words are individual fields in the rdma_msg structure. The fourth word is the first word of the rdma_body union which acts as the discriminator for the switched union. The contents of this field are described in Section 5.2.4.

These four fields must remain with the same meanings and in the same positions in all subsequent versions of the RPC-over-RDMA protocol.

### 5.2.1. Transaction ID (XID)

The XID generated for the RPC Call and Reply. Having the XID at a fixed location in the header makes it easy for the receiver to establish context as soon as each RPC-over-RDMA message arrives. This XID MUST be the same as the XID in the RPC message. The receiver MAY perform its processing based solely on the XID in the RPC-over-RDMA header, and thereby ignore the XID in the RPC message, if it so chooses.

### 5.2.2. Version Number

For RPC-over-RDMA Version One, this field MUST contain the value one (1). Rules regarding changes to this transport protocol version number can be found in Section 8.

### 5.2.3. Credit Value

When sent with an RPC Call message, the requested credit value is provided. When sent with an RPC Reply message, the granted credit value is returned. Further discussion of how the credit value is determined can be found in Section 4.3.

### 5.2.4. Procedure Number

- RDMA_MSG = 0 indicates that chunk lists and a Payload stream follow. The format of the chunk lists is discussed below.

- RDMA_NOMSG = 1 indicates that after the chunk lists there is no Payload stream. In this case, the chunk lists provide information to allow the responder to transfer the Payload stream using RDMA Read or Write operations.

- RDMA_MSGP = 2 is reserved.

- RDMA_DONE = 3 is reserved.

- RDMA_ERROR = 4 is used to signal an encoding error in the RPC-over-RDMA header.

An RDMA_MSG procedure conveys the Transport stream and the Payload stream via an RDMA Send operation. The Transport stream contains the four fixed fields, followed by the Read and Write lists and the Reply chunk, though any or all three MAY be marked as not present. The Payload stream then follows, beginning with its XID field. If a Read

or Write chunk list is present, a portion of the Payload stream has been excised and is conveyed separately via RDMA Read or Write operations.

An RDMA_NOMSG procedure conveys the Transport stream via an RDMA Send operation. The Transport stream contains the four fixed fields, followed by the Read and Write chunk lists and the Reply chunk. Though any of these MAY be marked as not present, one MUST be present and MUST hold the Payload stream for this RPC-over-RDMA message. If a Read or Write chunk list is present, a portion of the Payload stream has been excised and is conveyed separately via RDMA Read or Write operations.

An RDMA_ERROR procedure conveys the Transport stream via an RDMA Send operation. The Transport stream contains the four fixed fields, followed by formatted error information. No Payload stream is conveyed in this type of RPC-over-RDMA message.

A requester MUST NOT send an RPC-over-RDMA header with the RDMA_ERROR procedure. A responder MUST silently discard RDMA_ERROR procedures.

A gather operation on each RDMA Send operation can be used to combine the Transport and Payload streams, which might have been constructed in separate buffers. However, the total length of the gathered send buffers MUST NOT exceed the inline threshold.

## 5.3. Chunk Lists

The chunk lists in an RPC-over-RDMA Version One header are three XDR optional-data fields that follow the fixed header fields in RDMA_MSG and RDMA_NOMSG procedures. Read Section 4.19 of [RFC4506] carefully to understand how optional-data fields work. Examples of XDR encoded chunk lists are provided in Section 5.7 as an aid to understanding.

### 5.3.1. Read List

Each RDMA_MSG or RDMA_NOMSG procedure has one "Read list." The Read list is a list of zero or more Read segments, provided by the requester, that are grouped by their Position fields into Read chunks. Each Read chunk advertises the location of argument data the responder is to retrieve via RDMA Read operations. The requester has removed the data in these chunks from the call's Payload stream.

Via a Position Zero Read Chunk, a requester may provide an RPC Call message as a chunk in the Read list.

If the RPC Call has no argument data that is DDP-eligible and the Position Zero Read Chunk is not being used, the requester leaves the Read list empty.

Responders MUST leave the Read list empty in all replies.

### 5.3.2. Write List

Each RDMA_MSG or RDMA_NOMSG procedure has one "Write list." The Write list is a list of zero or more Write chunks, provided by the requester. Each Write chunk is an array of RDMA segments, thus the Write list is a list of counted arrays. Each Write chunk advertises receptacles for DDP-eligible data to be pushed by the responder via RDMA Write operations. If the RPC Reply has no possible DDP-eligible result data items, the requester leaves the Write list empty.

When a Write list is provided for the results of an RPC Call, the responder MUST provide data corresponding to DDP-eligible XDR data items via RDMA Write operations to the memory referenced in the Write list. The responder removes the data in these chunks from the reply's Payload stream.

When multiple Write chunks are present, the responder fills in each Write chunk with a DDP-eligible result until either there are no more results or no more Write chunks. The requester may not be able to predict which DDP-eligible data item goes in which chunk. Thus the requester is responsible for allocating and registering Write chunks large enough to accommodate the largest XDR data item that might be associated with each chunk in the list.

The RPC Reply conveys the size of result data items by returning each Write chunk to the requester with the segment lengths rewritten to match the actual data transferred. Decoding the reply therefore performs no local data copying but merely returns the length obtained from the reply.

Each decoded result consumes one entry in the Write list, which in turn consists of an array of RDMA segments. The length of a Write chunk is therefore the sum of all returned lengths in all segments comprising the corresponding list entry. As each Write chunk is decoded, the entire Write list entry is consumed.

A requester constructs the Write list for an RPC transaction before the responder has formulated its reply. When there is only one DDP-eligible result data item, the requester inserts only a single Write chunk in the Write list. If the responder populates that chunk with data, the requester knows with certainty which result data item is contained in it.

However, Upper Layer Protocol procedures may allow replies where more than one result data item is DDP-eligible. For example, an NFSv4 COMPOUND procedure is composed of individual NFSv4 operations, more than one of which may have a reply containing a DDP-eligible result.

As stated above, when multiple Write chunks are present, the responder reduces DDP-eligible results until either there are no more results or no more Write chunks. Then, as the requester decodes the reply Payload stream, it is clear from the contents of the reply which Write chunk contains which data item.

When a requester has provided a Write list in a Call message, the responder MUST copy that list into the associated Reply. The copied Write list in the Reply is modified as above to reflect the actual amount of data that is being returned in the Write list.

### 5.3.3. Reply Chunk

Each RDMA_MSG or RDMA_NOMSG procedure has one "Reply chunk." The Reply chunk is a Write chunk, provided by the requester. The Reply chunk is a single counted array of RDMA segments.

A requester MUST provide a Reply chunk whenever the maximum possible size of the reply message is larger than the inline threshold for messages from responder to requester. The Reply chunk MUST be large enough to contain a Payload stream (RPC message) of this maximum size. If the Transport stream and reply Payload stream together are smaller than the reply inline threshold, the responder MAY return it as a Short message rather than using the requester-provided Reply chunk.

When a requester has provided a Reply chunk in a Call message, the responder MUST copy that chunk into the associated Reply. The copied Reply chunk in the Reply is modified to reflect the actual amount of data that is being returned in the Reply chunk.

## 5.4. Memory Registration

RDMA requires that data is transferred between only registered memory segments at the source and destination. All protocol headers as well as separately transferred data chunks must reside in registered memory.

Since the cost of registering and de-registering memory can be a significant proportion of the RDMA transaction cost, it is important to minimize registration activity. For memory that is targeted by RDMA Send and Receive operations, a local-only registration is

sufficient and can be left in place during the life of a connection without any risk of data exposure.

### 5.4.1. Registration Longevity

Data transferred via RDMA Read and Write can reside in a memory allocation not in the control of the RPC-over-RDMA transport. These memory allocations can persist outside the bounds of an RPC transaction. They are registered and invalidated as needed, as part of each RPC transaction.

The requester endpoint must ensure that memory segments associated with each RPC transaction are properly fenced from responders before allowing Upper Layer access to the data contained in them. Moreover, the requester must not access these memory segments while the responder has access to them.

This includes segments that are associated with canceled RPCs. A responder cannot know that the requester is no longer waiting for a reply, and might proceed to read or even update memory that the requester might have released for other use.

### 5.4.2. Communicating DDP-Eligibility

The interface by which an Upper Layer Protocol implementation communicates the eligibility of a data item locally to its local RPC-over-RDMA endpoint is not described by this specification.

Depending on the implementation and constraints imposed by Upper Layer Bindings, it is possible to implement reduction transparently to upper layers. Such implementations may lead to inefficiencies, either because they require the RPC layer to perform expensive registration and de-registration of memory "on the fly", or they may require using RDMA chunks in reply messages, along with the resulting additional handshaking with the RPC-over-RDMA peer.

However, these issues are internal and generally confined to the local interface between RPC and its upper layers, one in which implementations are free to innovate. The only requirement, beyond constraints imposed by the Upper Layer Binding, is that the resulting RPC-over-RDMA protocol sent to the peer is valid for the upper layer.

### 5.4.3. Registration Strategies

The choice of which memory registration strategies to employ is left to requester and responder implementers. To support the widest array of RDMA implementations, as well as the most general steering tag scheme, an Offset field is included in each segment.

While zero-based offset schemes are available in many RDMA implementations, their use by RPC requires individual registration of each segment. For such implementations, this can be a significant overhead. By providing an offset in each chunk, many pre-registration or region-based registrations can be readily supported. By using a single, universal chunk representation, the RPC-over-RDMA protocol implementation is simplified to its most general form.

## 5.5. Error Handling

A receiver performs basic validity checks on the RPC-over-RDMA header and chunk contents before it passes the RPC message to the RPC consumer. If an incoming RPC-over-RDMA message is not as long as a minimal size RPC-over-RDMA header (28 bytes), the receiver cannot trust the value of the XID field, and therefore MUST silently discard the message before performing any parsing. If other errors are detected in the RPC-over-RDMA header of a Call message, a responder MUST send an RDMA_ERROR message back to the requester. If errors are detected in the RPC-over-RDMA header of a Reply message, a requester MUST silently discard the message.

To form an RDMA_ERROR procedure: The rdma_xid field MUST contain the same XID that was in the rdma_xid field in the failing request; The rdma_vers field MUST contain the same version that was in the rdma_vers field in the failing request; The rdma_proc field MUST contain the value RDMA_ERROR; The rdma_err field contains a value that reflects the type of error that occurred, as described below.

An RDMA_ERROR procedure indicates a permanent error. Receipt of this procedure completes the RPC transaction associated with XID in the rdma_xid field. A receiver MUST silently discard an RDMA_ERROR procedure that it cannot decode.

### 5.5.1. Header Version Mismatch

When a responder detects an RPC-over-RDMA header version that it does not support (currently this document defines only Version One), it MUST reply with an RDMA_ERROR procedure and set the rdma_err value to ERR_VERS, also providing the low and high inclusive version numbers it does, in fact, support.

### 5.5.2. XDR Errors

A receiver might encounter an XDR parsing error that prevents it from processing the incoming Transport stream. Examples of such errors include an invalid value in the rdma_proc field, an RDMA_NOMSG message that has no chunk lists, or the contents of the rdma_xid field might not match the contents of the XID field in the

accompanying RPC message. If the rdma_vers field contains a recognized value, but an XDR parsing error occurs, the responder MUST reply with an RDMA_ERROR procedure and set the rdma_err value to ERR_CHUNK.

When a responder receives a valid RPC-over-RDMA header but the responder's Upper Layer Protocol implementation cannot parse the RPC arguments in the RPC Call message, the responder SHOULD return a RPC_GARBAGEARGS reply, using an RDMA_MSG procedure. This type of parsing failure might be due to mismatches between chunk sizes or offsets and the contents of the Payload stream, for example. A responder MAY also report the presence of a non-DDP-eligible data item in a Read or Write chunk using RPC_GARBAGEARGS.

### 5.5.3. Responder RDMA Operational Errors

In RPC-over-RDMA Version One, it is the responder which drives RDMA Read and Write operations that target the requester's memory. Problems might arise as the responder attempts to use requester-provided resources for RDMA operations. For example:

- Chunks can be validated only by using their contents to form RDMA Read or Write operations. If chunk contents are invalid (say, a segment is no longer registered, or a chunk length is too long), a Remote Access error occurs.

- If a requester's receive buffer is too small, the responder's Send operation completes with a Local Length Error.

- If the requester-provided Reply chunk is too small to accommodate a large RPC Reply, a Remote Access error occurs. A responder can detect this problem before attempting to write past the end of the Reply chunk.

RDMA operational errors are typically fatal to the connection. To avoid a retransmission loop and repeated connection loss that deadlocks the connection, once the requester has re-established a connection, the responder should send an RDMA_ERROR reply with an rdma_err value of ERR_CHUNK to indicate that no RPC-level reply is possible for that XID.

### 5.5.4. Other Operational Errors

While a requester is constructing a Call message, an unrecoverable problem might occur that prevents the requester from posting further RDMA Work Requests on behalf of that message. As with other transports, if a requester is unable to construct and transmit a Call message, the associated RPC transaction fails immediately.

After a requester has received a reply, if it is unable to invalidate a memory region due to an unrecoverable problem, the requester MUST close the connection to fence that memory from the responder before the associated RPC transaction is complete.

While a responder is constructing a Reply message or error message, an unrecoverable problem might occur that prevents the responder from posting further RDMA Work Requests on behalf of that message. If a responder is unable to construct and transmit a Reply or error message, the responder MUST close the connection to signal to the requester that a reply was lost.

### 5.5.5. RDMA Transport Errors

The RDMA connection and physical link provide some degree of error detection and retransmission. iWARP's Marker PDU Aligned (MPA) layer (when used over TCP), Stream Control Transmission Protocol (SCTP), as well as the InfiniBand link layer all provide Cyclic Redundancy Check (CRC) protection of the RDMA payload, and CRC-class protection is a general attribute of such transports.

Additionally, the RPC layer itself can accept errors from the transport, and recover via retransmission. RPC recovery can handle complete loss and re-establishment of a transport connection.

The details of reporting and recovery from RDMA link layer errors are outside the scope of this protocol specification. See Section 9 for further discussion of the use of RPC-level integrity schemes to detect errors.

## 5.6. Protocol Elements No Longer Supported

The following protocol elements are no longer supported in RPC-over-RDMA Version One. Related enum values and structure definitions remain in the RPC-over-RDMA Version One protocol for backwards compatibility.

### 5.6.1. RDMA_MSGP

The specification of RDMA_MSGP in Section 3.9 of [RFC5666] is incomplete. To fully specify RDMA_MSGP would require:

- Updating the definition of DDP-eligibility to include data items that may be transferred, with padding, via RDMA_MSGP procedures

- Adding full operational descriptions of the alignment and threshold fields

- Discussing how alignment preferences are communicated between two peers without using CCP

- Describing the treatment of RDMA_MSGP procedures that convey Read or Write chunks

The RDMA_MSGP message type is beneficial only when the padded data payload is at the end of an RPC message's argument or result list. This is not typical for NFSv4 COMPOUND RPCs, which often include a GETATTR operation as the final element of the compound operation array.

Without a full specification of RDMA_MSGP, there has been no fully implemented prototype of it. Without a complete prototype of RDMA_MSGP support, it is difficult to assess whether this protocol element has benefit, or can even be made to work interoperably.

Therefore, senders MUST NOT send RDMA_MSGP procedures. When receiving an RDMA_MSGP procedure, responders SHOULD reply with an RDMA_ERROR procedure, setting the rdma_err field to ERR_CHUNK; requesters MUST silently discard the message.

### 5.6.2. RDMA_DONE

Because no implementation of RPC-over-RDMA Version One uses the Read-Read transfer model, there is never a need to send an RDMA_DONE procedure.

Therefore, senders MUST NOT send RDMA_DONE messages. Receivers MUST silently discard RDMA_DONE messages.

## 5.7. XDR Examples

RPC-over-RDMA chunk lists are complex data types. In this section, illustrations are provided to help readers grasp how chunk lists are represented inside an RPC-over-RDMA header.

An RDMA segment is the simplest component, being made up of a 32-bit handle (H), a 32-bit length (L), and 64-bits of offset (OO). Once flattened into an XDR stream, RDMA segments appear as

```
HLOO
```

A Read segment has an additional 32-bit position field. Read segments appear as

PHLOO

A Read chunk is a list of Read segments. Each segment is preceded by a 32-bit word containing a one if there is a segment, or a zero if there are no more segments (optional-data). In XDR form, this would look like

1 PHLOO 1 PHLOO 1 PHLOO 0

where P would hold the same value for each segment belonging to the same Read chunk.

The Read List is also a list of Read segments. In XDR form, this would look like a Read chunk, except that the P values could vary across the list. An empty Read List is encoded as a single 32-bit zero.

One Write chunk is a counted array of segments. In XDR form, the count would appear as the first 32-bit word, followed by an HLOO for each element of the array. For instance, a Write chunk with three elements would look like

3 HLOO HLOO HLOO

The Write List is a list of counted arrays. In XDR form, this is a combination of optional-data and counted arrays. To represent a Write List containing a Write chunk with three segments and a Write chunk with two segments, XDR would encode

1 3 HLOO HLOO HLOO 1 2 HLOO HLOO 0

An empty Write List is encoded as a single 32-bit zero.

The Reply chunk is a Write chunk. Since it is an optional-data field, however, there is a 32-bit field in front of it that contains a one if the Reply chunk is present, or a zero if it is not. After encoding, a Reply chunk with 2 segments would look like

1 2 HLOO HLOO

Frequently a requester does not provide any chunks. In that case, after the four fixed fields in the RPC-over-RDMA header, there are simply three 32-bit fields that contain zero.

## 6. RPC Bind Parameters

In setting up a new RDMA connection, the first action by a requester is to obtain a transport address for the responder. The mechanism used to obtain this address, and to open an RDMA connection is dependent on the type of RDMA transport, and is the responsibility of each RPC protocol binding and its local implementation.

RPC services normally register with a portmap or rpcbind [RFC1833] service, which associates an RPC Program number with a service address. (In the case of UDP or TCP, the service address for NFS is normally port 2049.) This policy is no different with RDMA transports, although it may require the allocation of port numbers appropriate to each Upper Layer Protocol that uses the RPC framing defined here.

When mapped atop the iWARP transport [RFC5040] [RFC5041], which uses IP port addressing due to its layering on TCP and/or SCTP, port mapping is trivial and consists merely of issuing the port in the connection process. The NFS/RDMA protocol service address has been assigned port 20049 by IANA, for both iWARP/TCP and iWARP/SCTP.

When mapped atop InfiniBand [IB], which uses a Group Identifier (GID)-based service endpoint naming scheme, a translation MUST be employed. One such translation is defined in the InfiniBand Port Addressing Annex [IBPORT], which is appropriate for translating IP port addressing to the InfiniBand network. Therefore, in this case, IP port addressing may be readily employed by the upper layer.

When a mapping standard or convention exists for IP ports on an RDMA interconnect, there are several possibilities for each upper layer to consider:

- One possibility is to have responder register its mapped IP port with the rpcbind service, under the netid (or netid's) defined here. An RPC-over-RDMA-aware requester can then resolve its desired service to a mappable port, and proceed to connect. This is the most flexible and compatible approach, for those upper layers that are defined to use the rpcbind service.

- A second possibility is to have the responder's portmapper register itself on the RDMA interconnect at a "well known" service address (on UDP or TCP, this corresponds to port 111). A requester could connect to this service address and use the

portmap protocol to obtain a service address in response to a program number, e.g., an iWARP port number, or an InfiniBand GID.

- Alternatively, the requester could simply connect to the mapped well-known port for the service itself, if it is appropriately defined. By convention, the NFS/RDMA service, when operating atop such an InfiniBand fabric, will use the same 20049 assignment as for iWARP.

Historically, different RPC protocols have taken different approaches to their port assignment; therefore, the specific method is left to each RPC-over-RDMA-enabled Upper Layer binding, and not addressed here.

In Section 10, this specification defines two new "netid" values, to be used for registration of upper layers atop iWARP [RFC5040] [RFC5041] and (when a suitable port translation service is available) InfiniBand [IB]. Additional RDMA-capable networks MAY define their own netids, or if they provide a port translation, MAY share the one defined here.

## 7. Upper Layer Binding Specifications

An Upper Layer Protocol is typically defined independently of any particular RPC transport. An Upper Layer Binding specification (ULB) provides guidance that helps the Upper Layer Protocol interoperate correctly and efficiently over a particular transport. For RPC-over-RDMA Version One, an Upper Layer Binding may provide:

- A taxonomy of XDR data items that are eligible for Direct Data Placement

- Constraints on which Upper Layer procedures may be reduced, and on how many chunks may appear in a single RPC request

- A method for determining the maximum size of the reply Payload stream for all procedures in the Upper Layer Protocol

- An rpcbind port assignment for operation of the RPC Program and Version on an RPC-over-RDMA transport

Each RPC Program and Version tuple that utilizes RPC-over-RDMA Version One needs to have an Upper Layer Binding specification.

### 7.1. DDP-Eligibility

An Upper Layer Binding designates some XDR data items as eligible for Direct Data Placement. As an RPC-over-RDMA message is formed, DDP-eligible data items can be removed from the Payload stream and placed directly in the receiver's memory.

An XDR data item should be considered for DDP-eligibility if there is a clear benefit to moving the contents of the item directly from the sender's memory to the receiver's memory. Criteria for DDP-eligibility include:

- The XDR data item is frequently sent or received, and its size is often much larger than typical inline thresholds.

- Transport-level processing of the XDR data item is not needed. For example, the data item is an opaque byte array, which requires no XDR encoding and decoding of its content.

- The content of the XDR data item is sensitive to address alignment. For example, pullup would be required on the receiver before the content of the item can be used.

- The XDR data item does not contain DDP-eligible data items.

In addition to defining the set of data items that are DDP-eligible, an Upper Layer Binding may also limit the use of chunks to particular Upper Layer procedures. If more than one data item in a procedure is DDP-eligible, the Upper Layer Binding may also limit the number of chunks that a requester can provide for a particular Upper Layer procedure.

Senders MUST NOT reduce data items that are not DDP-eligible. Such data items MAY, however, be moved as part of a Position Zero Read Chunk or a Reply chunk.

The programming interface by which an Upper Layer implementation indicates the DDP-eligibility of a data item to the RPC transport is not described by this specification. The only requirements are that the receiver can re-assemble the transmitted RPC-over-RDMA message into a valid XDR stream, and that DDP-eligibility rules specified by the Upper Layer Binding are respected.

There is no provision to express DDP-eligibility within the XDR language. The only definitive specification of DDP-eligibility is an Upper Layer Binding.

### 7.1.1. DDP-Eligibility Violation

A DDP-eligibility violation occurs when a requester forms a Call message with a non-DDP-eligible data item in a Read chunk. A violation occurs when a responder forms a Reply message without reducing a DDP-eligible data item when there is a Write list provided by the requester.

In the first case, a responder MUST NOT process the Call message.

In the second case, as a requester parses a Reply message, it must assume that the responder has correctly reduced a DDP-eligible result data item. If the responder has not done so, it is likely that the requester cannot finish parsing the Payload stream and that an XDR error would result.

Both types of violations MUST be reported as described in Section 5.5.2.

## 7.2. Maximum Reply Size

A requester provides resources for both a Call message and its matching Reply message. A requester forms the Call message itself, thus can compute the exact resources needed for it.

A requester must allocate resources for the Reply message (an RPC-over-RDMA credit, a Receive buffer, and possibly a Write list and Reply chunk) before the responder has formed the actual reply. To accommodate all possible replies for the procedure in the Call message, a requester must allocate reply resources based on the maximum possible size of the expected Reply message.

If there are procedures in the Upper Layer Protocol for which there is no clear reply size maximum, the Upper Layer Binding needs to specify a dependable means for determining the maximum.

## 7.3. Additional Considerations

There may be other details provided in an Upper Layer Binding.

- An Upper Layer Binding may recommend inline threshold values or other transport-related parameters for RPC-over-RDMA Version One connections bearing that Upper Layer Protocol.

- An Upper Layer Protocol may provide a means to communicate these transport-related parameters between peers. Note that RPC-over-RDMA Version One does not specify any mechanism for changing any

transport-related parameter after a connection has been established.

- Multiple Upper Layer Protocols may share a single RPC-over-RDMA Version One connection when their Upper Layer Bindings allow the use of RPC-over-RDMA Version One and the rpcbind port assignments for the Protocols allow connection sharing. In this case, the same transport parameters (such as inline threshold) apply to all Protocols using that connection.

Each Upper Layer Binding needs to be designed to allow correct interoperation without regard to the transport parameters actually in use. Furthermore, implementations of Upper Layer Protocols must be designed to interoperate correctly regardless of the connection parameters in effect on a connection.

### 7.4. Upper Layer Protocol Extensions

An RPC Program and Version tuple may be extensible. For instance, there may be a minor versioning scheme that is not reflected in the RPC version number. Or, the Upper Layer Protocol may allow additional features to be specified after the original RPC program specification was ratified.

Upper Layer Bindings are provided for interoperable RPC Programs and Versions by extending existing Upper Layer Bindings to reflect the changes made necessary by each addition to the existing XDR.

## 8. Protocol Extensibility

The RPC-over-RDMA header format is specified using XDR, unlike the message header used with RPC over TCP. To maintain a high degree of interoperability among implementations of RPC-over-RDMA, any change to this XDR requires a protocol version number change. New versions of RPC-over-RDMA may be published as separate protocol specifications without updating this document.

The first four fields in every RPC-over-RDMA header must remain aligned at the same fixed offsets for all versions of the RPC-over-RDMA protocol. The version number must be in a fixed place to enable implementations to detect protocol version mismatches.

For version mismatches to be reported in a fashion that all future version implementations can reliably decode, the rdma_proc field must remain in a fixed place, the value of ERR_VERS must always remain the same, and the field placement in struct rpc_rdma_errvers must always remain the same.

### 8.1. Conventional Extensions

Introducing new capabilities to RPC-over-RDMA Version One is limited to the adoption of conventions that make use of existing XDR (defined in this document) and allowed abstract RDMA operations. Because no mechanism for detecting optional features exists in RPC-over-RDMA Version One, implementations must rely on Upper Layer Protocols to communicate the existence of such extensions.

Such extensions must be specified in a Standards Track document with appropriate review by the nfsv4 Working Group and the IESG. An example of a conventional extension to RPC-over-RDMA Version One is the specification of backward direction message support to enable NFSv4.1 callback operations, described in [I-D.ietf-nfsv4-rpcrdma-bidirection].

## 9. Security Considerations

### 9.1. Memory Protection

A primary consideration is the protection of the integrity and privacy of local memory by an RPC-over-RDMA transport. The use of RPC-over-RDMA MUST NOT introduce any vulnerabilities to system memory contents, nor to memory owned by user processes.

It is REQUIRED that any RDMA provider used for RPC transport be conformant to the requirements of [RFC5042] in order to satisfy these protections. These protections are provided by the RDMA layer specifications, and in particular, their security models.

#### 9.1.1. Protection Domains

The use of Protection Domains to limit the exposure of memory segments to a single connection is critical. Any attempt by an endpoint not participating in that connection to re-use memory handles needs to result in immediate failure of that connection. Because Upper Layer Protocol security mechanisms rely on this aspect of Reliable Connection behavior, strong authentication of remote endpoints is recommended.

#### 9.1.2. Handle Predictability

Unpredictable memory handles should be used for any operation requiring advertised memory segments. Advertising a continuously registered memory region allows a remote host to read or write to that region even when an RPC involving that memory is not under way. Therefore implementations should avoid advertising persistently registered memory.

### 9.1.3. Memory Fencing

Requesters should register memory segments for remote access only when they are about to be the target of an RPC operation that involves an RDMA Read or Write.

Registered memory segments should be invalidated as soon as related RPC operations are complete. Invalidation and DMA unmapping of RDMA segments should be complete before message integrity checking is done, and before the RPC consumer is allowed to continue execution and use or alter the contents of a memory region.

An RPC transaction on a requester might be terminated before a reply arrives if the RPC consumer exits unexpectedly (for example it is signaled or a segmentation fault occurs). When an RPC terminates abnormally, memory segments associated with that RPC should be invalidated appropriately before the segments are released to be reused for other purposes on the requester.

## 9.2. RPC Message Security

ONC RPC provides cryptographic security via the RPCSEC_GSS framework [I-D.ietf-nfsv4-rpcsec-gssv3]. RPCSEC_GSS implements message authentication, per-message integrity checking, and per-message confidentiality. However, integrity and privacy services require significant movement of data on each endpoint host. Some performance benefits enabled by RDMA transports can be lost.

### 9.2.1. RPC-Over-RDMA Protection At Lower Layers

Note that performance loss is expected when RPCSEC_GSS integrity or privacy is in use on any RPC transport. Protection below the RDMA layer is a more appropriate security mechanism for RDMA transports in performance-sensitive deployments. Certain configurations of IPsec can be co-located in RDMA hardware, for example, without any change to RDMA consumers or loss of data movement efficiency.

The use of protection in a lower layer MAY be negotiated through the use of an RPCSEC_GSS security flavor defined in [I-D.ietf-nfsv4-rpcsec-gssv3] in conjunction with the Channel Binding mechanism [RFC5056] and IPsec Channel Connection Latching [RFC5660]. Use of such mechanisms is REQUIRED where integrity and/or privacy is desired and where efficiency is required.

### 9.2.2. RPCSEC_GSS On RPC-Over-RDMA Transports

Not all RDMA devices and fabrics support the above protection mechanisms. Also, per-message authentication is still required on NFS clients where multiple users access NFS files. In these cases, RPCSEC_GSS can protect NFS traffic conveyed on RPC-over-RDMA connections.

RPCSEC_GSS extends the ONC RPC protocol [RFC5531] without changing the format of RPC messages. By observing the conventions described in this section, an RPC-over-RDMA transport can convey RPCSEC_GSS-protected RPC messages interoperably.

As part of the ONC RPC protocol, protocol elements of RPCSEC_GSS that appear in the Payload stream of an RPC-over-RDMA message (such as control messages exchanged as part of establishing or destroying a security context, or data items that are part of RPCSEC_GSS authentication material) MUST NOT be reduced.

#### 9.2.2.1. RPCSEC_GSS Context Negotiation

Some NFS client implementations use a separate connection to establish a GSS context for NFS operation. These clients use TCP and the standard NFS port (2049) for context establishment. However there is no guarantee that an NFS/RDMA server provides a TCP-based NFS server on port 2049.

#### 9.2.2.2. RPC-Over-RDMA With RPCSEC_GSS Authentication

The RPCSEC_GSS authentication service has no impact on the DDP-eligibity of data items in an Upper Layer Protocol.

However, RPCSEC_GSS authentication material appearing in an RPC message header can be larger than, say, an AUTH_SYS authenticator. In particular, when an RPCSEC_GSS pseudoflavor is in use, a requester needs to accommodate a larger RPC credential when marshaling Call messages, and to provide for a maximum size RPCSEC_GSS verifier when allocating reply buffers and Reply chunks.

RPC messages, and thus Payload streams, are made larger as a result. Upper Layer Protocol operations that fit in a Short Message when a simpler form of authentication is in use might need to be reduced, or conveyed via a Long Message, when RPCSEC_GSS authentication is in use. It is more likely that a requester provides both a Read list and a Reply chunk in the same RPC-over-RDMA header to convey a Long call and provision a receptacle for a Long reply. More frequent use of Long messages can impact transport efficiency.

#### 9.2.2.3. RPC-Over-RDMA With RPCSEC_GSS Integrity Or Privacy

The RPCSEC_GSS integrity service enables endpoints to detect modification of RPC messages in flight. The RPCSEC_GSS privacy service prevents all but the intended recipient from viewing the cleartext content of RPC arguments and results. RPCSEC_GSS integrity and privacy are end-to-end. They protect RPC arguments and results from application to server endpoint, and back.

The RPCSEC_GSS integrity and encryption services operate on whole RPC messages after they have been XDR encoded for transmit, and before they have been XDR decoded after receipt. Both sender and receiver endpoints use intermediate buffers to prevent exposure of encrypted data or unverified cleartext data to RPC consumers. After verification, encryption, and message wrapping has been performed, the transport layer MAY use RDMA data transfer between these intermediate buffers.

The process of reducing a DDP-eligible data item removes the data item and its XDR padding from the encoded XDR stream. XDR padding of a reduced data item is not transferred in an RPC-over-RDMA message. After reduction, the Payload stream contains fewer octets then the whole XDR stream did beforehand. XDR padding octets are often zero bytes, but they don't have to be. Thus reducing DDP-eligible items affects the result of message integrity verification or encryption.

Therefore a sender MUST NOT reduce a Payload stream when RPCSEC_GSS integrity or encryption services are in use. Effectively, no data item is DDP-eligible in this situation, and Chunked Messages cannot be used. In this mode, an RPC-over-RDMA transport operates in the same manner as a transport that does not support direct data placement.

When RPCSEC_GSS integrity or privacy is in use, a requester provides both a Read list and a Reply chunk in the same RPC-over-RDMA header to convey a Long call and provision a receptacle for a Long reply.

#### 9.2.2.4. Protecting RPC-Over-RDMA Transport Headers

Like the base fields in an ONC RPC message (XID, call direction, and so on), the contents of an RPC-over-RDMA message's Transport stream are not protected by RPCSEC_GSS. This exposes XIDs, connection credit limits, and chunk lists (but not the content of the data items they refer to) to malicious behavior, which could redirect data that is transferred by the RPC-over-RDMA message, result in spurious retransmits, or trigger connection loss.

In particular, if an attacker alters the information contained in the chunk lists of an RPC-over-RDMA header, data contained in those chunks can be redirected to other registered memory segments on requesters. An attacker might alter the arguments of RDMA Read and RDMA Write operations on the wire to similar effect. The use of RPCSEC_GSS integrity or privacy services enable the requester to detect if such tampering has been done and reject the RPC message.

Encryption at lower layers, as described in Section 9.2.1, protects the content of the Transport stream. To address attacks on RDMA protocols themselves, RDMA transport implementations should conform to [RFC5042].

## 10. IANA Considerations

Three assignments are specified by this document. These are unchanged from [RFC5666]:

- A set of RPC "netids" for resolving RPC-over-RDMA services
- Optional service port assignments for Upper Layer Bindings
- An RPC program number assignment for the configuration protocol

These assignments have been established, as below.

The new RPC transport has been assigned an RPC "netid", which is an rpcbind [RFC1833] string used to describe the underlying protocol in order for RPC to select the appropriate transport framing, as well as the format of the service addresses and ports.

The following "Netid" registry strings are defined for this purpose:

```
NC_RDMA "rdma"
NC_RDMA6 "rdma6"
```

These netids MAY be used for any RDMA network satisfying the requirements of Section 3.2.2, and able to identify service endpoints using IP port addressing, possibly through use of a translation service as described above in Section 6. The "rdma" netid is to be used when IPv4 addressing is employed by the underlying transport, and "rdma6" for IPv6 addressing.

The netid assignment policy and registry are defined in [RFC5665].

As a new RPC transport, this protocol has no effect on RPC Program numbers or existing registered port numbers. However, new port numbers MAY be registered for use by RPC-over-RDMA-enabled services, as appropriate to the new networks over which the services will operate.

For example, the NFS/RDMA service defined in [RFC5667] has been assigned the port 20049, in the IANA registry:

```
nfsrdma 20049/tcp Network File System (NFS) over RDMA
nfsrdma 20049/udp Network File System (NFS) over RDMA
nfsrdma 20049/sctp Network File System (NFS) over RDMA
```

The RPC program number assignment policy and registry are defined in [RFC5531].

## 11. Acknowledgments

The editor gratefully acknowledges the work of Brent Callaghan and Tom Talpey on the original RPC-over-RDMA Version One specification [RFC5666].

Dave Noveck provided excellent review, constructive suggestions, and consistent navigational guidance throughout the process of drafting this document. Dave also contributed much of the organization and content of Section 8 and helped the authors understand the complexities of XDR extensibility.

The comments and contributions of Karen Deitke, Dai Ngo, Chunli Zhang, Dominique Martinet, and Mahesh Siddheshwar are accepted with great thanks. The editor also wishes to thank Bill Baker, Greg Marsden, and Matt Benjamin for their support of this work.

The extract.sh shell script and formatting conventions were first described by the authors of the NFSv4.1 XDR specification [RFC5662].

Special thanks go to nfsv4 Working Group Chair Spencer Shepler and nfsv4 Working Group Secretary Thomas Haynes for their support.
