Session

The Reliable Multicast Transport (RMT) working group has chartered to standardize IP multicast transport services. This draft is concerned with the requirements of the tree-based protocol [WCPKT00]. In particular, this draft defines a block for auto-configuration of a tree comprised of a Sender, Service Nodes, and Receivers into a tree (called a

INTERNET DRAFT [draft-ietf-rmt-bb-track-01.txt](#)

2

INTERNET DRAFT [draft-ietf-rmt-bb-tree-config-03.txt](#)

November 2002

the trees

Tree in this document). The design goals of this draft are motivated by the needs of TRACK-based protocols, however it constructs are useful for other services.

in this

This building block can be interfaced to any other BB or PI wishing to use a tree structure. To actually use this BB's features, the PI needs to includes the messages described

found

BB in its packets. An example of how to use this BB can be in the TRACK PI[WCPKT01].

IP
multicast
service model
routing

The process of session tree construction is difficult for multicast. The best session trees match the underlying routing tree topology [[LPG98](#)], however the multicast [[DEE89](#)] does not provide explicit support for discovering tree topology.

not
and
Generic
the use
It
several
network

Furthermore, deployed multicast architectures can vary; for example, hosts may be restricted to multicast reception and transmission with Source-Specific multicast routing [[HC00](#)]; routers may provide special extended routing services with Router Assist [[CST00](#)]. The RMT charter does not restrict of any particular network service in constructing the tree. It only suggests preferred scenarios. Accordingly, there are viable solutions for constructing a tree, depending on conditions.

such as
depth
this

The optimality of a tree may also depend on other factors, the need for load balancing, and the need to minimize the when used for collecting feedback information. The goal of building block is to specify a distributed procedure for automatically constructing a tree that is loop-free and as efficient as possible given the information available.

construction in
routing
which
discovery and
within this
affects the

This draft describes a unified solution for tree the presence of different multicast service models and protocols. In particular, it specifies a single procedure may be used with various techniques for service node distance measurements, several of which are specified document. The difference in these techniques primarily optimality of the tree. The unified algorithm ensures that

different implementations can interoperate and construct a loop-free tree.

In order to accommodate various multicast deployments, this document divides the tree building process into the following

major components:

1. Several techniques for discovering neighboring service nodes.

In particular: Static, Expanding Ring Search, and Mesh.

Discovering neighboring service nodes is a necessary condition for getting connected, so each node in the session

INTERNET DRAFT [draft-ietf-rmt-bb-track-01.txt](#)

3

INTERNET DRAFT [draft-ietf-rmt-bb-tree-config-03.txt](#)

November 2002

must implement at least one of the above techniques.

2. Several algorithms for selecting neighboring service nodes.

In particular, the measurement and use of neighbor distance and sender distance are described. These service node selection algorithms help produce a good tree.

3. A single distributed procedure for construction and maintenance of loop-free Session Trees.

1.1 Terminology

The key words "MUST", "MUST NOT", "REQUIRED", "SHALL", "SHALL NOT", "SHOULD", "SHOULD NOT", "RECOMMENDED", "MAY", and "OPTIONAL" in this document are to be interpreted as described in [RFC 2119](#).

Session

A session is used to distribute data over a multicast address. A Session Tree is used to provide reliability and feedback services for a session.

Sender

Sender is the

The single sender of data on a multicast session. The root of the Session Tree.

Receiver

A receiver receives data from the sender via the multicast session.

Session Identifier

creates

the

this

A fixed-size number, chosen either by the application that the session or by the transport. Senders and Receivers use Session Identifier to distinguish sessions. The size of number is specified by the Protocol Instantiation (PI).

Service Node (SN)

and

Sender. The

tree.

designed to

trees, or

session. SNS

and MAY

Child

Children for a

as Repair

A node within the tree which receives and retransmits data, aggregates and forwards control information toward the Sender operates as the root Service Node in any session Service Nodes MAY be dedicated servers within a network participate in multiple Sessions and support multiple they MAY be Receivers participating in an individual MAY limit the number of Children they choose to service, also make other restrictions on the characteristics of each (distance, location, etc.). An SN that has accepted session is called a Parent. In other documents, Service Node is sometimes referred to

Head (RH).

Session Tree (ST)

multicast

more

as leaf

of

session may

The Session Tree is a tree spanning all receivers of a session. It is rooted at the Sender, consisting of zero or more Service Nodes as interior nodes, and zero or more receivers nodes. An ST is constructed for the forwarding of control information back to the Sender as well as for the resending missed data to the Receivers. The ST for a particular change over the course of the session.

Parent

the path

the

its

through

same

to the

A Parent is an SN or Receiver's predecessor in the ST on toward the Sender. Every SN or Receiver on the tree except Sender itself has a parent. Each Parent communicates with children using either an assigned multicast address or unicast. If a multicast address is used, this may be the address used by the session, or one specifically assigned Parent.

Children

is

The set of Receivers and SNs for which an SN or the Sender providing repair and feedback services.

Tree Level

from the

their

connected to

128.

for

used to

A number indicating the number of "generations" a node is root. The sender is at $TL=0$. Those that use the sender as parent are at $TL=1$ and so on. When a receiver is not the tree yet, it has a tree level value greater or equal to 128. The reason for reserving part of the space (of tree levels) indicating "off-tree" is so that special measures can be

range of
tree, its
level.

prevent forming loops. The largest value is 255, so the
off-tree levels are in the range 128 - 255. Initially, all
receivers have a TL value of 128. Once a Node joins the
Tree Level is updated to be one more than its Parent's

Distance Metric

nodes
of
Distance

There are several techniques to quantify distances between
(Receivers, SNs, and the Sender) in a session. Each type
quantification is called a distance metric. Several
Metrics are described in this draft.

Sender Distance

The distance from a node to the Sender.

INTERNET DRAFT [draft-ietf-rmt-bb-track-01.txt](#)

5

INTERNET DRAFT [draft-ietf-rmt-bb-tree-config-03.txt](#)

November 2002

Neighbor Distance

The distance from a node to a Neighbor.

Neighbor

to the

A node's (Receiver or SN) Neighbors are SNs that are close
node, according to the Distance Metric(s) used by the node.

1.2 Assumptions

following

This document describes how to build trees under the
conditions:

- a. The multicast group has only a single sender.
- b. A single SN can serve multiple sessions.
- c. Sessions can take advantage of a pre-deployed

infrastructure

session

of SNs (ones that are not necessarily aware of a
before the receivers), or recruit Receivers to be SNs.

Search[YGS95] d. Generic Router Assist[CST00] and Expanding Ring

are not required of the network infrastructure, but if available they should be able to be utilized.

1.3 Requirements

The following are specifically required:

- from the
- independent of the
- tree.
- a. While tree-building may take advantage of information routing layer, the mechanisms described are routing protocol(s) used by the underlying multicast
 - b. All trees constructed must be loop-free
 - c. These mechanisms must support late joiners and tree optimization

1.4 Applicability Statement

very

manual

well.

The authors recognize that automatic tree construction is a difficult problem. Nonetheless, complete reliance on configuration is very user unfriendly and error prone as

loop-

information

available.

This building block describes a procedure for constructing free trees when there is minimal manual configured

configurations

necessarily

optimally.

This is analogous to providing a system with default that allow the system to work correctly, but not

BB does

There are many possible criteria for tree optimality. This

The tree construction procedure does allow manual various distance measurement techniques to be selectively independently applied for different subgroups of receivers to achieve incremental improvement to the quality of the

is
load

There are many other criteria for tree-building than what described in this document, for instance, methods based on balancing and minimizing feedback latency.

[2. Overview](#)

The tree building process described within this document builds logical trees which consist of:

1. A root node (the Sender)
2. Intermediate nodes (Service Nodes or SNs) which may be either Receivers or nodes specifically allocated to the task of repair and aggregation
3. Leaf nodes which are Receivers only

Session trees are spanning trees rooted at the Sender. trees can be used for the forwarding of control information (i.e. ACKs) towards the root, or for forwarding of data (i.e. repairs) towards the leaf nodes.

Session trees are constructed per Sender; each node wishing to join the tree discovers its neighboring SNs and then selects its best parent based on locally available information, such as the relative

INTERNET DRAFT [draft-ietf-rmt-bb-track-01.txt](#)

7

INTERNET DRAFT [draft-ietf-rmt-bb-tree-config-03.txt](#)

November 2002

sender distances and neighbor distances. This document specifies several techniques for measuring distances.

It is important to note that SNs may be actual Receivers (e.g. Receivers willing and able to also function as SNs) or pre-deployed "specialized" servers that are signaled to join the tree by Receivers. We use the term Service Node to refer to either a Receiver or "server" which is participating as part of the logical tree formation.

Tree construction, regardless of SN discovery and selection algorithm, proceeds generically as follows.

1. Session Announcement

mechanisms

Receiver

address,

construction.

as the

the

Receivers of a session use standard out-of-band

for discovery of a session's existence (e.g. Session Advertisement ([[HPW00](#)], URL, etc). In this way, a

discovers the multicast group address, the Sender's

and other information necessary for logical tree

Sessions may be announced in two parts, the first part containing generic information about the session, such

multicast address, and the second part, announced on

multicast address, containing additional information.

2. Measurements to the Sender (optional)

optionally

All SNs and Receivers that know about the session

determine their distance to the Sender.

3. Neighbor Discovery

(candidate

November 2002

the tree if it has not already, discovering an SN of
its own, possibly using a different method than leaf Receivers.

6. Optimization (optional) and Fault Recovery

During a session, a Receiver or SN may change to a
different SN for a number of reasons described below, including
fault tolerance. The Session Tree is maintained and
optimized over time.

This building block provides mechanisms for maintaining and
optimizing the tree, as well as tearing it down when the
Sender is done with it. In the rest of this document, the term
'Node'
denotes a Receiver or SN.

following the given order by sending a BindRequestmessage,

INTERNET DRAFT [draft-ietf-rmt-bb-track-01.txt](#)

INTERNET DRAFT [draft-ietf-rmt-bb-tree-config-03.txt](#)

then waits for the responding message such as BindConfirm or BindReject from TC. These binding steps will be done according to the TRACK mechanism, as described in the TRACK PI [[WCMKT02](#)].

In the Static algorithm, SN discovery with a TC proceeds as follows:

1. The node joins the multicast session and learns of the location of TC (from the session announcement).
2. The node optionally discovers its distance from the Sender. Any metric described in [Section 4.2](#) may be used.
3. The node sends a Query message to the TC for a parent. The request includes (optionally) the node's distance to the parent. The sender and whether the node functions as an SN or not.
4. The TC chooses one or more candidate parents (SNs) for the node from the active SNs by its own tree configuration rule. The selection of candidate parents may be done by comparing the network prefix or by referring to any other information such as the number of currently attached children, etc.
5. The TC MUST responds to the Query message with an Advertise message, which include the candidate parent list. In the list, each entry contains the corresponding IP address and port of an SN.

All the entries in the list SHOULD be arranged in decreasing order of preference levels.

In the rejection case, the Advertise message does not include any candidate parent. In this case, the Node

may resort to the other mechanism such as ERS and Mesh.

seconds.

message per SolicitPeriod. When SN's responds to QUERY it also suppresses its ADVERTISE message if one has been sent less than SolicitPeriod ago. This parameter is used to control the amount of control traffic during tree construction if used.

- BetweenQuery: This is the time interval a node must wait before sending successive Query messages.
- MaxBindAttempts: This variable is an integer used to control how many times a receiver tries to bind to a SN before giving up and try another one.
- BindPeriod: In order to prevent loops, sometimes a SN must reject a BindRequest (for example, when the SN is not on the tree yet and has a BindRequest outstanding itself) from a receiver. In this case, if the receiver needs to retry binding to the same SN again (perhaps because the receiver does not discover any alternative SN's), then it must wait for BindPeriod seconds.

4.1.3 Mesh

The mesh approach relies on a set of SN's already deployed as

session announcement to the multicast receivers.

Then, the

sender's SN binds to the sender by sending a

BindRequest

message.

During the internal processings of Sender-SN binding

described

until now, any Query and Advertise messages are not used.

When a session starts, the bindings between SN and

Receivers will

be done. The tree binding of SN-receiver is done with the

Tree

Configurator (TC), which was used in the Static algorithm.

The

main difference between Static algorithm with TC and Mesh algorithm with TC is that the active SNs are considered as candidate SNs in the Static scheme, while the pre-deployed SNs are considered as candidates in the Mesh scheme. That

is, in

the Mesh scheme, the TC is required to already get the

information

on the locations of the pre-deployed SNs.

Then the tree buildings between receivers and SNs are done

as

follows:

1. When a session starts, a receiver sends a Query

message to

the TC. The receiver may optionally discovers its

distance

from the Sender. Any metric described in [Section 4.2](#)

may be

used.

2. The TC chooses one or more candidate parents SNs for

the

receiver from the pre-deployed SNs by its own tree configuration rule, as described in [Section 4.1.1](#).

3. TC MUST respond to the Query message with an

Advertise

message, which include the candidate parent list. In

the list,

each entry contains the corresponding IP address and

port of

the parent.

the

BindRequest

messages based on the candidate parent list, as
described in

[Section 5](#).

bindings

provider's

its

some

back-up

that the

Once a receiver is connected to a parent SN, the SN-SN
will also be done internally by the pre-configured
policy. For example, each SN in the mesh tries to bind to
"next-hop" SN. If the "next-hop" SN is not reachable for
reason, an SN may also try to bind to any neighbor SN as a
alternative. These procedures will be devised to ensure
loop freedom is guaranteed in [section 5](#).

[4.2. Distance Measurement](#)

between

Different techniques can be used to determine distances
nodes in a session. The distances of interest are:

Sender distance - the distance from a SN to sender

Neighbor distance - the distance from a receiver to a
neighboring SN

if several

These distances can be used in selecting a Service Node
are discovered.

specific way

Metrics are

These techniques quantify distance differently. Each
of quantifying distance is called a metric. Different
not necessarily comparable. For example, if distance

between A

Y

and B is X using metric m1, and distance between A and C is using metric m2, then $X > Y$ does not necessarily imply B is farther from A than C.

ranked.

sender.
close to

the tree
used,

sender.

One metric a receiver can use for SN selection is the levels the SN is from the sender. For example, given two close proximity to a receiver, if one SN is n levels from sender and the other is m levels, where $m < n$, the receiver select the SN with m levels. This is because a shallower allows faster propagation of feedback information to the (Note, we assumed the choice is between two SN's equally the receiver. The receiver to SN distance is another consideration).

The number of levels metric is not generally available, as may be constructed bottom up. If the mesh approach is however, the distance in the SN's forwarding tables can be implemented as an estimate of the number of levels from the sender.

[4.2.3](#) Delay

the SN is
simply be
the SN is
be the
added in
proximity to a
delay to
the

used. If the
although it
information

Another metric is the delay from an SN to the sender. If directly connected to the sender, then the delay would be the time to send feedback from the SN to the sender. If several levels down from the sender, then the delay would be the sum of the delays for each level (with some jitter time each level). For example, given two SN's in close proximity to a receiver, the receiver SHOULD select the SN with a smaller delay to the sender. This is again for the purpose of minimizing feedback time.

If the tree is built bottom up, this metric cannot be used. If the mesh approach is used, this metric can be implemented, requires the SN's in the mesh to exchange distance

based on the delay metric.

4.2.4 Address

determined
common with
if its
querying

For IPv6 addresses[HOD98], distance can be approximately by the number of aggregation levels one address has in another. For this metric, one node is closer than another address has more aggregation levels in common with the node's address.

4.2.5 Static

4.3 Service Node Selection

best one

Once Neighbors have been discovered, a node selects the using whatever distance information is available.

best SN
loop

If there is no sender distance information to compare, the is simply the one that is closest to the node, without a being formed by binding the node to the SN.

If sender distances are available, there are two cases:

Leaf nodes: For leaf nodes, the goal is to use the closest SN possible.

SNs: For SNs joining the tree, it is important to pick an SN that is closer to the sender; neighbor distance is a secondary factor.

Once an SN has been selected, the node tries to bind to it as described in [Section 5](#). Loop prevention is done during the bind process using only Tree Level information.

This algorithm is recommended because it assigns each node the closest SN, and does not require all nodes to measure their sender distance at the start of the session. Depending on the selected metric, multiple nodes measuring sender distance could cause message implosion, and delay tree construction. On the other hand, the SNs selected may actually be further from the Sender than their children are. However, it may be necessary to assign nodes to non-optimal SNs in order to get them on the tree, since it is possible that no SN closer to the Sender can accept any more children.

Alternatively, nodes may be required to measure sender distance before selecting an SN in order to ensure that each parent is closer to the Sender than its children. Presumably, this results in a tree in which parents detect message loss before their children, minimizing repair requests.

prevented from

The following is a detailed description of the tree

process. All tree construction follows this pattern. The

differences between instantiations of this building block

how nodes discover and select neighbors.

Once an SN has been selected, the Node sends a BindRequest

to the SN. If the SN has an outstanding request to bind to

SN, it must refuse the incoming bind request in case it

a loop.

Otherwise, it MAY accept the Node as a child as long as

it would not cause a loop in the tree. Loop freedom is

by these two rules:

1. If the requesting node does not have children, the SN
accept it as a child as long as the SN has no
bind requests. If it does have an outstanding bind
the SN can accept the node as a child if its address is
than the child's address.
2. If the requesting node has children, the SN can accept
a child if
 - a. the SN's level is 128, i.e., it is the top of a sub-
yet connected to the Sender, or
 - b. the SN's level is less than 128, i.e., it is connected
Sender.

The second rule prevents a node from selecting one of its

children as its parent. Two nodes at level 128 are

selecting each other using tie-breaking criteria described

step 1

above.

BindConfirm

If the SN accepts the Node as a Child, it returns a

BindReject

message. If it does not accept the Node, it sends a

select the

message. If the Node does not receive a response after
MaxBindAttempts tries every BindPeriod seconds, it MAY

repair the tree. Nodes may need to have specific information about availability before selecting a Parent.

maximum Service Nodes MAY limit the number of children they support depending on their capacity. Once an SN has accepted its number of children, it stops accepting new children until a change in membership causes its count of children to go below this limit.

reserve If an SN limits the number of children it supports, it MUST at least one child slot for other SNs. This guarantees the growth of the repair tree.

6. Tree Maintenance

Node. Tree maintenance is an ongoing process active in every as the Because the tree is based on the operation of SNs, as well various underlying metrics that may change over time, it is important that these dependencies be monitored for changes. Nodes MUST monitor Parents for liveness and changes in tree level, and SHOULD continue to run the Neighbor Discovery and Selection process in order to optimize their choice of SN. Parents must also monitor Children for liveness.

6.1 Monitoring Parents and Children

8. External Interfaces

This section describes external interfaces for the building block.

8.1 Interfaces to this BB.

These may be used by a PI, or by a higher-level BB.

8.1.1 start(boolean SN, advertisement)

parameter is start notifies the BB to begin operation. If the SN set to TRUE, the BB also starts SN operation.

8.1.2 end()

end notifies the BB to end operation.

8.1.3 incomingMessage(message)

from the PI. This interface is used to pass an incoming message down

8.1.4 getStatistics

or PI. getStatistics returns current BB statistics to the upper BB

8.1.5 getSns

with a getSns instructs the BB to start the process of finding SN candidates for this node. getSns may return immediately list of
