Reorder Density and Reorder Buffer-occupancy Density - Metrics for Packet Reordering Measurements

Status of this Memo

By submitting this Internet-Draft, each author represents that any applicable patent or other IPR claims of which he or she is aware have been or will be disclosed, and any of which he or she becomes aware will be disclosed, in accordance with [Section 6 of BCP 79](#).

This document is an Internet-Draft and is subject to all provisions of [section 3 of BCP 78](#).

Internet-Drafts are working documents of the Internet Engineering Task Force (IETF), its areas, and its working groups. Note that other groups may also distribute working documents as Internet-Drafts.

Internet-Drafts are draft documents valid for a maximum of six months and may be updated, replaced, or obsoleted by other documents at any time. It is inappropriate to use Internet-Drafts as reference material or to cite them other than as "work in progress."

Abstract

Out-of-order arrival of packets is a common occurrence on the Internet, and it will become more widespread as link speeds increase.

A good reorder metric will capture the occurrence and characteristics of reordering comprehensively, and will have broader utility than merely distinguishing among different reordered sequences.

Jayasumana, et al.
1]

[Page

Two metrics for packet reordering are presented, namely, Reorder Density (RD) and Reorder Buffer-occupancy Density (RBD). A threshold is used to clearly define when a packet is considered lost, to bound computational complexity at $O(N)$, and to keep the memory requirement for evaluation independent of N , where N is the length of the packet sequence. RD is a comprehensive metric that captures the characteristics of reordering, while RBD evaluates the sequences from the point of view of recovery from reordering. These metrics are simple to compute yet comprehensive in their characterization of packet reordering. The measures are robust and orthogonal to packet loss and duplication.

1. Introduction and Motivation

Packet reordering is a phenomena that occurs in Internet Protocol (IP) networks. Major causes of packet reordering include, but are not limited to, packet stripping at layers 2 and 3 [[1,2](#)], priority scheduling (e.g., Diffserv), and route fluttering [[3,4](#)]. Reordering leads to degradation of the performance of many applications [[1,6,7](#)].

For example, perceived voice quality degrades if a Voice over IP (VoIP) application receives packets out-of-order packets. Increased link speeds, increased parallelism within routers and switches, QoS support, and load balancing among links all point to increased packet reordering in future networks.

Effective metrics for reordering are required to measure and quantify reordering. A good metric or a set of metrics capturing the nature of reordering can be expected to provide insight into the reordering phenomenon in networks. It may be possible to use such metrics to predict the effects of reordering on applications that are sensitive to packet reorder, and perhaps even to compensate for reordering. A metric for reordered packets, may also help evaluate network protocols and implementations with respect to their impact on packet reordering.

The percentage of out-of-order packets is often used as a metric for characterizing reordering. However, this metric is vague and lacks in detail. Further, there is no uniform definition for the degree of reordering of an arrived packet [[8,9](#)]. For example, consider the two packet sequences (1, 3, 4, 2, 5) and (1, 4, 3, 2, 5). It is possible to interpret the reordering of packets in these sequences differently. For example,

- (i) Packets 2, 3 and 4 are out-of-order in both cases.
- (ii) Only packet 2 is out-of-order in the first sequence, while packets 2 and 3 are out-of-order in the second.
- (iii) Packets 3 and 4 are out-of-order in both the sequences.
- (iv) Packets 2, 3 and 4 are out-of-order in the first sequence, while packets 4 and 2 are out-of-order in the second sequence.

In essence, the percentage of out-of-order packets as a metric of reordering is subject to interpretation and cannot capture the reordering unambiguously and hence, accurately.

Other metrics attempt to overcome this ambiguity by defining only the late packets or only the early packets as being reordered. However,

measuring reordering based only on late or only on early packets is not always effective. Consider, for example the sequence (1, 20, 2, 3, ..., 19, 21, 22, ...); the only anomaly is that packet 20 is delivered immediately after packet 1. A metric based only on lateness will indicate a high degree of reordering, even though in

this example it is a single packet arriving ahead of others. Similarly, a metric based only on earliness does not accurately capture reordering caused by a late arriving packet. A complete reorder metric must account for both earliness and lateness, and must

be able to differentiate between the two. The inability to capture both the earliness and the lateness precludes a metric from being useful for estimating end-to-end reordering based on reordering in constituent subnets.

The sensitivity to packet reordering can vary significantly from one application to the other. Consider again the packet sequence (1, 3, 4, 2, 5). If buffers are available to store packets 3 and 4 while waiting for packet 2, an application can recover from reordering. However, with certain real-time applications, the arrival of packet

2 out of order may render it useless. While one can argue that a good packet reordering measurement scheme should capture application-specific effects, a counter argument can also be made that packet reordering should be measured strictly with respect to the order of delivery independent of the application.

2. Attributes Packet Reordering Metrics

The first and foremost requirement of a packet reorder metric is its ability to capture the amount and extent of reordering in a sequence of packets. The fact that a measure varies with reordering of

packets in a stream does not make it a good metric. The usefulness and effectiveness of a metric will depend on a number of attributes:

a) Simplicity

An ideal metric is one that is simple to understand and evaluate, and yet informative, i.e., able to provide a complete picture of

reordering. Percentage of packets reordered is the simplest singleton metric; But the ambiguity in its definition as discussed

earlier, and its failure to carry the extent of reordering make it

less informative. On the other hand, keeping track of the displacements of each and every packet without compressing the data will contain all the information about reordering, but it is not simple to evaluate or use.

A simpler metric may be preferred in some cases even though it does not capture reordering completely, while other cases may demand more complex, yet complete metric.

In striving to strike a balance, the lateness based metrics

consider only the late packets as reordered, and earliness based metrics only the early packets as reordered. A metric based only on earliness or only on lateness however captures only a part of

information associated with reordering. Consider the sequence (1, 15, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14). An earliness based metric is considers one out of 15 packets as out of order, while a lateness-based metric would indicate all the packets from 2 to 14 to be out of order, even though it is more likely that a single packet arrived early. A metric capturing both early and late arrivals in contrast provides a complete picture of reordering in a sequence.

b) Low Sensitivity to Packet Loss and Duplication

A reorder metric should treat only an out-of-order packet as reordered, i.e., if a packet is lost during transit then this should not result in its following packets, which arrive in order, to be classified as out of order. Consider the sequence (1, 3, 4, 5, 6). If packet 2 has been lost, the sequence should not be considered to contain any out-of-order packets. Similarly, if multiple copies of a packet (duplicates) are delivered, this must not result in a packet being classified as out of order, as long as one copy arrives in the proper position. For example, sequence (1, 2, 3, 2, 4, 5) has no reordering. The lost and duplicate packet counts may be tracked using metrics specifically to measure those, e.g., percentage of lost packets, and percentage of duplicate packets.

c) Low evaluation complexity

Memory and time complexities associated with evaluating a metric play a vital role in implementation and real-time measurements. Spatial/memory complexity corresponds to the amount of buffers required for the overall measurement process, whereas time/computation complexity refers to the number of computation steps involved in computing the amount of reordering in a sequence. On-the-fly evaluation of the metric for large streams of packets requires the computational complexity to be $O(N)$, where N is the number of packets. This allows the metric to be updated in constant-time as each packet arrives. In the absence of a threshold defining losses or the number of sequence numbers to buffer for detection of duplicates, the worst-case complexity of loss and duplication detection will increase with N . The rate of increase will depend among other things on the value of N and the implementation of duplicate detection scheme.

d) Robustness

Reorder measurement should be robust against different network phenomena and peculiarities in measurement or sequences such as a very late arrival of a duplicate packet, or even a rogue packet

due to an error or sequence number wrap-around. The impact due to

Jayasumana, et al.
5]

[Page

an event associated with a single or a small number of packets should have a sense of proportionality on the reorder measure. Consider for example, the arrival sequence: (1, 5430, 2, 3, 4, 5,..) where packet 5430 appears to be very early; it may be either due to sequence rollover in test streams or some unknown reason.

e) Broad applicability

A framework for IP performance metrics [5] states: "The metrics must aid users and providers in understanding the performance they experience or provide."

Rather than being a mere value or a set of values that changes with the reordering of packets in a stream, a reorder metric should be useful for a variety of purposes. An application or a transport protocol implementation, for example, may be able to use

the reordering information to allocate resources to recover from reordering. A metric may be useful for TCP flow control, buffer resource allocation for recovery from reordering and /or network diagnosis.

The ability to combine the reorder metrics of constituent subnets to provide the end to end reordering would be an extremely useful property. In the absence of this property, no amount of individual network measurements short of measuring the reordering for the pair of endpoints of interest would be useful in predicting the end-to-end reordering.

3. Reorder Density and Reorder Buffer-occupancy Density

In this memo, we define two discrete density functions, Reorder Density (RD) and Reorder Buffer-occupancy Density (RBD), that capture

the nature of reordering in a packet stream. These two metrics can be used individually or collectively to characterize the reordering in a packet stream. Also presented are algorithms for real-time evaluation of these metrics for an incoming packet stream.

RD is defined as the distribution of displacements of packets from their original positions, normalized with respect to the number of packets. An early packet corresponds to a negative displacement and a late packet to a positive displacement. Lost and duplicate packets are accounted for when evaluating these displacements.

The ability of RD to capture the nature and properties of reordering in a comprehensive manner has been demonstrated in [9, 10, 15]. The RD observed at the output port of a subnet when the input is an

in-order packet stream, can be viewed as a "reorder response" of a network, a concept somewhat similar to the "system response" or

Jayasumana, et al.
6]

[Page

"impulse response" used in traditional system theory. For a subnet under stationary conditions, RD is the probability density of the packet displacement. RD measured on individual subnets can be combined, using the convolution operation, to predict the end-to-end

reorder characteristics of the network formed by the cascade of subnets under a fairly broad set of conditions [10]. RD also shows significant promise as a tool for analytical modeling of reordering, as demonstrated with a load-balancing scenario in [17]. Use of a threshold to define the condition under which a packet is considered lost, makes the metric robust, efficient and adaptable for different network and stream characteristics.

RBD is the normalized histogram of the occupancy of a hypothetical buffer that would allow the recovery from out-of-order delivery of packets. If an arriving packet is early, it is added to a hypothetical buffer until it can be released in order [8]. The occupancy of this buffer after each arrival is used as the measure of

reordering. A threshold, used to declare a packet as lost, keeps the

complexity of computation within bounds. The threshold may be selected based on application requirements in situations where the late arrival of a packet makes it useless, e.g., a real-time applications. In [8], this metric was called RD and buffer occupancy

was known as displacement.

RD and RBD are simple, yet useful, metrics that for measurement and evaluation of reordering. These metrics are robust against many peculiarities, such as those discussed previously, and have a computational complexity of $O(N)$, where N is the received sequence size. RD is orthogonal to loss and duplication, whereas RBD is orthogonal to duplication.

A detailed comparison of these and other proposed metrics for reordering is presented in [15].

The following terms are used to formally define RD, RBD, and the measurement algorithms. Wraparound of sequence numbers is not explicitly addressed in this document, but with the use of modulo- N arithmetic, all claims made here remain valid in the presence of wraparound.

3.1 Receive_index (RI)

Consider a sequence of packets (1, 2, ..., N) transmitted over a network. A receive_index RI (1, 2, ...), is a value assigned to a packet as it arrives at its destination according to the order of arrival. A receive_index is not assigned to duplicate packets, and the receive_index value skips the value corresponding to a lost

packet. (The detection of loss and duplication for this purpose is described in [section 6](#).) In the absence of reordering, the sequence

Jayasumana, et al.
7]

[Page

number of the packet and the receive_index are the same for each packet.

RI is used to compute earliness and lateness of an arriving packet. Below are two examples of received sequences with receive_index values for a sequence of 5 packets (1, 2, 3, 4, 5) arriving out of order:

Example 1:

Arrived sequence:	2	1	4	5	3
Receive_index:	1	2	3	4	5

Example 2:

Arrived sequence:	1	4	3	5	3
Receive_index:	1	3	4	5	-

In Example 1, there is no loss or duplication. In Example 2, the packet with sequence number 2 is lost, thus 2 is not assigned as an RI; packet 3 is duplicated, thus the second copy is not assigned an RI.

3.2 Out-of-Order Packet

When the sequence number of a packet is not equal to the RI assigned to it, it is considered an out-of-order packet. Duplicates for which an RI is not defined are ignored.

3.3 Displacement (D)

Displacement (D) of a packet is defined as the difference between RI and the sequence number of the packet, i.e., the displacement of packet i is $RI[i] - i$. Thus, a negative displacement indicates the earliness of a packet and a positive displacement to the lateness. In example 3 below, an arrived sequence with displacements of each packet is illustrated.

Example 3:

Arrived sequence:	1	4	3	5	3	8	7	6
Receive_index:	1	3	4	5	-	6	7	8
Displacement:	0	-1	1	0	-	-2	0	2

3.4 Displacement Threshold (DT)

The displacement threshold is a threshold on the displacement of packets that allows the metric to classify a packet as lost or duplicate. Determining when to classify a packet as lost is difficult because there is no point in time at which a packet can definitely be classified as lost; the packet may still arrive after some arbitrarily long delay. However, from a practical point of view, a packet may be classified as lost if it has not arrived within

a certain administratively defined displacement threshold, DT. Similarly, to identify a duplicate packet, it is theoretically necessary to keep track of all the arrived (or missing) packets. Again, however, from a practical point of view, missing packets within a certain window of sequence numbers suffice. Thus, DT is used as a practical means for declaring a packet as lost or duplicated. DT makes the metric more robust, keeps the computational complexity for long sequences within $O(N)$, and keeps storage requirements independent of N .

If DT is selected too small, reordered packets might be classified as lost. A large DT will increase both the size of memory required to keep track of sequence numbers and the length of computation time required to evaluate the metric. Indeed, it is possible to use two different thresholds for the two cases. The selection of DT is further discussed in [section 5](#).

[3.5](#) Displacement Frequency (FD)

Displacement Frequency $FD[k]$ is the number of arrived packets having a displacement of k , where k takes values from $-DT$ to DT .

[3.6](#) Reorder Density (RD)

RD is defined as the distribution of the Displacement Frequencies $FD[k]$, normalized with respect to N' , where N' is the length of the received sequence, ignoring lost and duplicate packets. N' is equal to the $\sum(FD[k])$ for k in $[-DT, DT]$.

[3.7](#) Expected Packet (E)

A packet with sequence number E is expected if E is the largest number such that all the packets with sequence numbers less than E have already arrived or have been determined to be lost.

[3.8](#) Buffer Occupancy (B)

An arrived packet with a sequence number greater than that of an expected packet is considered to be stored in a hypothetical buffer sufficiently long to permit recovery from reordering. At any packet arrival instant, the buffer occupancy is equal to the number of out-of-order packets in the buffer, including the newly arrived packet. One buffer location is assumed for each packet, although it is possible to extend the concept to the case where the number of bytes is used for buffer occupancy. For example, consider the sequence of packets (1, 2, 4, 5, 3) with expected order (1, 2, 3, 4, 5). When packet 4 arrives the buffer occupancy is 1 because packet 4 arrived early. Similarly, the buffer occupancy becomes 2 when packet 5 arrives. When packet 3 arrives, recovery from reordering occurs and the buffer occupancy reduces to zero.

3.9 Buffer Occupancy Threshold (BT)

Buffer occupancy threshold is a threshold on the maximum size of the hypothetical buffer that is used for recovery from reordering. As with the case of DT for RD, BT is used for loss and duplication classification for Reorder Buffer-occupancy Density (RBD) computation (see [section 3.11](#)). BT provides robustness, and limits the computation complexity of RBD.

3.10 Buffer Occupancy Frequency (FB)

At the arrival of each packet the buffer occupancy may take any value k ranging from 0 to BT. The buffer occupancy frequency $FB[k]$ is the number of arrival instances after which the occupancy takes the value of k .

3.11 Reorder Buffer-Occupancy Density (RBD)

Reorder buffer-occupancy density is the buffer occupancy frequencies normalized by the total number of non-duplicate packets, i.e., $RBD[k] = FB[k]/N'$ where N' is the length of the received sequence, ignoring excessively delayed (deemed lost) and duplicate packets. N' is also the $\text{sum}(FB[k])$ for all k such that k belongs to $[0, BT]$.

4. Representation of Packet Reordering and Reorder Density

Consider a sequence of packets (1, 2, ..., N). Let the RI assigned to packet m be the sequence number m plus some non-negative offset dm , i.e., $(m + dm)$. A reorder event of packet m is represented by $r(m, dm)$. When dm is not equal to zero, a reorder event is said to have occurred. A packet is late if $dm > 0$ and early if $dm < 0$. Thus, packet reordering of a sequence of packets is completely represented by the union of reorder events, R , referred to as the reorder set:

$$R = \{r(m, dm) \mid dm \text{ not equal to } 0 \text{ for all } m\}$$

If there is no reordering in a packet sequence then R is the null set.

Examples 4 and 5 illustrate the reorder set:

Example 4. No losses or duplicates

Arrived Sequence	1	2	3	5	4	6
Receive_index	1	2	3	4	5	6
Displacement	0	0	0	-1	1	0

$R = \{(4,1), (5,-1)\}$

Example 5. Packet 4 is lost and 2 is duplicated

Arrived Sequence	1	2	5	3	6	2
Receive_index	1	2	3	5	6	-
Displacement	0	0	-2	2	0	-

R = {(3, 2), (5, -2)}

RD is defined as the discrete density of the frequency of packets with respect to their displacements, i.e., the lateness and earliness from the original position. Let S[k] denote the set of reorder events in R with displacement equal to k, i.e.,

$$S[k] = \{r(m, dm) \mid dm = k\}$$

Let |S[k]| be the cardinality of set S[k]. Thus, RD[k] is defined as

|S[k]| normalized with respect to the total number of received packets (N'). Note that N' does not include duplicates or lost packets.

$$RD[k] = |S[k]| / N' \text{ for } k \text{ not equal to zero.}$$

RD[0] corresponds to the packets for which RI is the same as the sequence number:

$$RD[0] = 1 - \sum(|S[k]| / N')$$

As defined previously, FD[k] is the measure that keeps track of |S[k]|.

5. Selection of DT

Although assigning a threshold for determining lost and duplicate packets might appear to introduce error into the reorder metrics, in practice this need not be the case. Applications, protocols, and the

network itself operate within finite resource constraints which introduce practical limits beyond which the choice of certain values become irrelevant. In the case of DT, it is common to find a value above which DT does not have an impact on the reorder metrics. For example, in case of a VoIP application with a bit-rate of 128kbps and

packet size of 200 bytes, a practical DT value can be determined as follows. Assume that the application can wait a maximum of 50 ms for an expected packet and that the packets arrive at constant rate. Within 50 ms, the application can receive $(128 \times 1000 \times 0.05) / (200 \times 8)$, i.e., 4 packets. Since packets arriving after this duration are effectively lost, the DT value could be set at 4. If the operational nature of an application is such that a DT can be defined, then using DT in the computation of reorder metrics

will not invalidate nor limit the effectiveness of the metrics,
i.e.,
increasing DT does not provide any benefit. In the case of TCP, the

Jayasumana, et al.
11]

[Page

transmit and receive window sizes impose a natural limit on the useful value of DT. Sequence number wraparound may provide a useful upper bound for DT in some instances.

If there are no operational constraints imposed by factors as described above, or if one is purely interested in a more complete picture of reordering, then DT can be made as large as required. If DT is equal to the length of the packet sequence (worst case scenario), a complete picture of reordering is seen. Any metric that does not rely on a threshold to declare a packet as lost, implicitly makes one of two assumptions: a) A missing packet is not considered lost until the end of the sequence, or b) the packet is considered lost until it arrives. Former corresponds to the case where DT is set to the length of the sequence. Latter leads to many problems related to complexity and robustness.

6. Detection of Lost and Duplicate Packets

In RD, a packet is considered lost if it is late beyond DT. Non-duplicate arriving packets do not have a copy in the buffer and do not have a sequence number less (earlier) than E. In RBD, a packet is considered lost if the buffer is filled to its threshold BT. A packet is considered a duplicate when the sequence number is less than the expected packet, or if the sequence number is already in the buffer.

Since RI skips the sequence number of a lost packet, the question arises as to how to assign an RI to subsequent packets that arrive before it is known that the packet is lost. This problem arises only when reorder metrics are calculated in real-time for an incoming sequence, and not with offline computations. This concern can be handled in one of two ways:

a) Go-back Method: RD is computed as packets arrive. When a packet is deemed lost, RI values are corrected and displacements recomputed.

The Go-back Method is only invoked when a packet is lost, and re-computing involves at most DT packets.

b) Stay-back Method: RD evaluation lags the arriving packets so that the correct RI and E values can be assigned to each packet as it arrives. Here, RI is assigned to a packet only once, and the value assigned is guaranteed to be correct. In the worst case, the computation lags arriving packet by DT. The lag associated with the

Stay-back Method is incurred only when a packet is missing.

Another issue related to a metric and its implementation is the robustness against peculiarities that may occur in a sequence as discussed in [Section 2](#). Consider for example, the arrival sequence:

(1, 5430, 2, 3, 4, 5, ...). With RD, a sense of proportionality is maintained easily using the concept of threshold (DT) and to limit

Jayasumana, et al.
12]

[Page

the effect of a rogue packet to this threshold. With RD, for example, as its displacement is greater than threshold, it is discarded. This way the impact due to the rogue packet, 5430, is limited at most to DT packets, thus imposing a limit on the amount of error it can cause in results. Note also that a threshold different from DT can be used for this purpose. By limiting the time a packet to remain in the buffer according to a prespecified threshold, RBD can be made robust against rogue packets as well.

7. Algorithms to evaluate RD and RBD

The algorithms to compute RD and RBD are given below. These algorithms are applicable for on-line computation of an incoming packet stream, and provide an up-to-date metric for the packet stream

so far. For simplicity, the sequence numbers are considered to start

from 1 and continue in increments of 1. Only the Stay-back Method of loss detection is presented here, hence the RD values lag by a maximum of DT. Algorithm for go-back method is given in [14]. Perl scripts for these algorithms are posted in [11].

7.1 Algorithm for RD

Variables used:

```
-----  
RI: receive_index.  
S: Arrival under consideration for lateness/earliness computation.  
D: Lateness or earliness of the packet being processed.  
FD[ -DT..DT]: Frequency of lateness and earliness.  
window[1..DT+1]: List of incoming sequence numbers.  
buffer[1..DT]: Array to hold sequence numbers of early arrivals.  
window[] and buffer[] are empty at the beginning.  
=====
```

Step 1. Initialize:

```
Store first unique DT+1 sequence numbers in arriving order into  
window;  
RI = 1;
```

Step 2. Repeat (until window is empty):

```
If (window or buffer contains sequence number RI)  
{  
    Copy first sequence number in window to S;  
    Delete first sequence number from window;  
    D = RI - S; # compute displacement
```

```
If (absolute(D) <= DT) # Apply threshold
{
    FD[D]++; # Update frequency

    If (buffer contains sequence number RI)
        Delete RI from buffer;

    If (D < 0) # Early Arrival
        add S to empty slot in buffer;
    RI++; # Update RI value
}

Else # Displacement beyond threshold.
{
    Discard S;
}
# Get next incoming non-duplicate sequence number, if any.
newS = get_next_arrival(); # subroutine called*
if (newS != null)
{
    add newS to window;
}
if (window is empty) go to step 3;
}
Else # RI not found. Get next RI value.
{
    # Next RI is the minimum among window and buffer contents.
    m = minimum (minimum (window), minimum (buffer));
    If (RI < m)
        RI = m;
    Else
        RI++;
}
}
```

Step 3. Normalize FD to get RD;

```
# Get a new sequence number from packet stream, if any
subroutine get_next_arrival()
{
    do # get non-duplicate next arrival
    {
        newS = new sequence from arriving stream;
        if (newS == null) # End of packet stream
            return null;
    } while (newS < RI or newS in buffer or newS in window);

    return newS;
}
```

7.2 RBD Algorithm

Variables used:

```
-----  
# E : Next expected sequence number.  
# S : Sequence number of the packet just arrived.  
# B : Current buffer occupancy.  
# BT: Buffer Occupancy threshold.  
# FB[i]: Frequency of buffer occupancy i (0 <= i <= BT).  
# in_buffer(N) : True if the packet with sequence number N is  
  already stored in the buffer.
```

- ```
=====
```
1. Initialize  $E = 1$ ,  $B = 0$  and  $FB[i] = 0$  for all values of  $i$ .
  2. Do the following for each arrived packet.

```
 If (in_buffer(S) || S < E) /*Do nothing*/;
 /* Case a: S is a duplicate or excessively delayed packet.
 Discard the packet.*/
 Else
 {

 If (S == E)
 /* Case b: Expected packet has arrived.*/
 {
 E = E + 1;
 While (in_buffer(E))
 {
 B = B - 1; /* Free buffer occupied by E.*/
 E = E + 1; /* Expect next packet.*/
 }
 FB[B] = FB[B] + 1; /*Update frequency for buffer
 occupancy B.*/
 } /* End of ElseIf (S == E)*/

 ElseIf (S > E)
 /* Case c: Arrived packet has a sequence number higher
 than expected.*/
 {
 If (B < BT)
 /* Store the arrived packet in a buffer.*/
 B = B + 1;
 Else
 /* Expected packet is delayed beyond the BT.
 Treat it as lost.*/
 {
 Repeat
 {
```

```

 E = E + 1;
 }
 Until (in_buffer(E) || E == S);

 While (in_buffer(E) || E == S)
 {
 if (E != S) B = B - 1;
 E = E + 1;
 }
}
FB[B] = FB[B] + 1; /*Update frequency for buffer
occupancy B.*/
} /* End of ElseIf (S > E)*/

}

```

3. Normalize FB[i] to obtain RBD[i], for all values of i using

$$RBD[i] = \frac{FB[i]}{\text{Sum}(FB[j] \text{ for } 0 \leq j \leq BT)}$$

## 8. Examples

a. Scenario with no packet loss

Consider the sequence of packets (1, 4, 2, 5, 3, 6, 7, 8) with DT = BT = 4.

Tables 1 and 2 show the computational steps when the RD algorithm is applied to the above sequence.

-----  
 Table 1: Late/Early-packet Frequency computation steps  
 -----

|       |   |    |   |    |   |   |   |   |
|-------|---|----|---|----|---|---|---|---|
| S     | 1 | 4  | 2 | 5  | 3 | 6 | 7 | 8 |
| RI    | 1 | 2  | 3 | 4  | 5 | 6 | 7 | 8 |
| D     | 0 | -2 | 1 | -1 | 2 | 0 | 0 | 0 |
| FD[D] | 1 | 1  | 1 | 1  | 1 | 2 | 3 | 4 |

-----  
 (S, RI,D and FD[D] as described in [section 7.1](#))  
 -----

The last row (FD[D]) represents the current frequency of occurrence of the displacement D, e.g., column 3 indicates FD[1] = 1 while column 4 indicates FD[-1] = 1. The final set of values for RD are shown in Table 2.

-----  
 Table 2: Reorder Density (RD)  
 -----

|       |       |       |     |       |       |
|-------|-------|-------|-----|-------|-------|
| D     | -2    | -1    | 0   | 1     | 2     |
| FD[D] | 1     | 1     | 4   | 1     | 1     |
| RD[D] | 0.125 | 0.125 | 0.5 | 0.125 | 0.125 |

(D,FD[D] and RD[D] as described in [section 7.1](#))  
 -----

Tables 3 and 4 illustrate the computational steps for RBD for the same example.

-----  
 Table 3: Buffer occupancy frequencies (FB) computation steps  
 -----

|       |   |   |   |   |   |   |   |   |
|-------|---|---|---|---|---|---|---|---|
| S     | 1 | 4 | 2 | 5 | 3 | 6 | 7 | 8 |
| E     | 1 | 2 | 2 | 3 | 3 | 6 | 7 | 8 |
| B     | 0 | 1 | 1 | 2 | 0 | 0 | 0 | 0 |
| FB[B] | 1 | 1 | 2 | 1 | 2 | 3 | 4 | 5 |

(E,S,B and FB[B] as described in [section 7.2](#))  
 -----

-----  
 Table 4: Reorder Buffer-occupancy Density  
 -----

|        |       |      |       |
|--------|-------|------|-------|
| B      | 0     | 1    | 2     |
| FB[B]  | 5     | 2    | 1     |
| RBD[B] | 0.625 | 0.25 | 0.125 |

(B,FB[B] and RBD[B] as discussed in [section 7.2](#))  
 -----

Graphical representations of the densities are as follows:

b. Scenario with packet loss

Consider a sequence of 6 packets (1, 2, 4, 5, 6, 7) with  $DT = BT =$

3.

Table 5 shows the computational steps when the RD algorithm is applied to the above sequence to obtain  $FD[D]$ .

-----  
 Table 5: Late/Early-packet Frequency computation steps  
 -----

|         |   |   |   |   |   |   |
|---------|---|---|---|---|---|---|
| S       | 1 | 2 | 4 | 5 | 6 | 7 |
| RI      | 1 | 2 | 4 | 5 | 6 | 7 |
| D       | 0 | 0 | 0 | 0 | 0 | 0 |
| $FD[D]$ | 1 | 2 | 3 | 4 | 5 | 6 |

-----  
 (S,RI,D and  $FD[D]$  as described in [section 7.1](#))  
 -----

Table 6 illustrates the  $FB[B]$  for the above arrival sequence.

-----  
 Table 6: Buffer occupancy computation steps  
 -----

|         |   |   |   |   |   |   |   |
|---------|---|---|---|---|---|---|---|
| S       | 1 | 2 | 4 | 5 | 6 | 7 |   |
| E       | 1 | 2 | 3 | 3 | 3 | 7 |   |
| B       |   | 0 | 0 | 1 | 2 | 3 | 0 |
| $FB[B]$ | 1 | 2 | 1 | 1 | 1 | 3 |   |

-----  
 (E,S,B and  $FB[B]$  as described in [section 7.2](#))  
 -----

Graphical representations of RD and RBD for the above sequence are as follows.

c. Scenario with duplicate packets

Consider a sequence of 6 packets (1, 3, 2, 3, 4, 5) with  $DT = 2$ . Tables 7 shows the computational steps when the RD algorithm is applied to the above sequence to obtain  $FD[D]$ .

-----  
 Table 7: Late/Early-packet Frequency computation steps  
 -----

|       |   |    |   |   |   |   |
|-------|---|----|---|---|---|---|
| S     | 1 | 3  | 2 | 3 | 4 | 5 |
| RI    | 1 | 2  | 3 | - | 4 | 5 |
| D     | 0 | -1 | 1 | - | 0 | 0 |
| FD[D] | 1 | 1  | 1 | - | 2 | 3 |

-----  
 (S, RI,D and FD[D] as described in [section 7.1](#))  
 -----

Table 8 illustrates the FB[B] for the above arrival sequence.

-----  
 Table 8: Buffer Occupancy Frequency computation steps  
 -----

|       |   |   |   |   |   |   |
|-------|---|---|---|---|---|---|
| S     | 1 | 3 | 2 | 3 | 4 | 5 |
| E     | 1 | 2 | 2 | - | 4 | 5 |
| B     | 0 | 1 | 0 | - | 0 | 0 |
| FB[B] | 1 | 1 | 2 | - | 3 | 4 |

-----  
 (E,S,B and FB[B] as described in [section 7.2](#))  
 -----

Graphical representations of RD and RBD for the above sequence are as follows:

## 9. Comparison with Other Metrics

RD and RBD are compared to other metrics that are being proposed [\[12\]](#) in [\[15\]](#). This section is for review purposes only and will be removed from the final draft.

## **10. Security Considerations**

This document does not define any protocol. The metric definition per se is believed to have no security implications.

## **11. IANA Considerations**

This document requires nothing from the IANA.
