The memory-hard Argon2 password hash function  
draft-josefsson-argon2-00

## Abstract

This document describes the Argon2 memory-hard function for password hashing and other applications. We provide a implementer oriented description together with sample code and test vectors. The purpose is to simplify adoption of Argon2 for Internet protocols.

## Status of This Memo

This Internet-Draft is submitted in full conformance with the provisions of [BCP 78](#) and [BCP 79](#).

Internet-Drafts are working documents of the Internet Engineering Task Force (IETF). Note that other groups may also distribute working documents as Internet-Drafts. The list of current Internet-Drafts is at <http://datatracker.ietf.org/drafts/current/>.

Internet-Drafts are draft documents valid for a maximum of six months and may be updated, replaced, or obsoleted by other documents at any time. It is inappropriate to use Internet-Drafts as reference material or to cite them other than as "work in progress."

## [1.](#) Introduction

This document describes the Argon2 memory-hard function for password hashing and other applications. We provide a implementer oriented description together with sample code and test vectors. The purpose is to simplify adoption of Argon2 for Internet protocols.

Argon2 summarizes the state of the art in the design of memory-hard functions. It is a streamlined and simple design. It aims at the highest memory filling rate and effective use of multiple computing units, while still providing defense against tradeoff attacks. Argon2 is optimized for the x86 architecture and exploits the cache and memory organization of the recent Intel and AMD processors. Argon2 has two variants: Argon2d and Argon2i. Argon2d is faster and uses data-depending memory access, which makes it suitable for cryptocurrencies and applications with no threats from side-channel

timing attacks. Argon2i uses data-independent memory access, which is preferred for password hashing and password-based key derivation. Argon2i is slower as it makes more passes over the memory to protect from tradeoff attacks.

For further background and discussion, see the Argon2 paper [[ARGON2](#)].

## [2.](#) Notation and Conventions

$x^y$  ---  $x$  multiplied by itself  $y$  times

$a*b$  --- multiplication of  $a$  and  $b$

$c-d$  --- subtraction of  $c$  with  $d$

$E_f$  --- variable  $E$  with subscript index  $f$

$g / h$  ---  $g$  divided by  $h$

$I(j)$  --- function  $I$  evaluated on parameters  $j$

$K || L$  --- string  $K$  concatenated with string  $L$

## [3.](#) Argon2 Algorithm

### [3.1.](#) Argon2 Inputs and Outputs

Argon2 have the following input parameters:

- o Message string  $P$ , typically a password. May have any length from 0 to  $2^{32} - 1$  bytes.
- o Nonce  $S$ , typically a random salt. May have any length from 8 to  $2^{32} - 1$  bytes. 16 bytes is recommended for password hashing. See [[RFC4086](#)] for discussion about randomness.
- o Degree of parallelism  $p$  determines how many independent (but synchronizing) computational chains can be run. It may take any integer value from 1 to 255.
- o Tag length  $T$  may be any integer number of bytes from 4 to  $2^{32}-1$ .

- o Memory size  $m$  can be any integer number of kilobytes from  $8 \times p$  to  $2^{32}-1$ . The actual number of blocks is  $m'$ , which is  $m$  rounded down to the nearest multiple of  $4 \times p$ .
- o Number of iterations  $t$  (used to tune the running time independently of the memory size) can be any integer number from 1 to  $2^{32}-1$ .
- o Version number  $v$  is one byte  $0x10$ .

- o Secret value  $K$  (serves as key if necessary, but we do not assume any key use by default) may have any length from 0 to 32 bytes.
- o Associated data  $X$  may have any length from 0 to  $2^{32}-1$  bytes.
- o Type  $y$  of Argon2: 0 for Argon2d, 1 for Argon2i.

The Argon2 output is a  $T$ -length string.

### [3.2.](#) Argon2 Operation

Argon2 uses an internal compression function  $G$  with two 1024-byte inputs and a 1024-byte output, and an internal hash function  $H$ . Here  $H$  is the Blake2b [[I-D.saarinen-blake2](#)] hash function, and the compression function  $G$  is based on its internal permutation. A variable-length hash function  $H'$  built upon  $H$  is also used.  $G$  and  $H'$  are described in later section.

The Argon2 operation is as follows.

1. Establish  $H_0$  as the 64-bit value as shown in the figure below.  $H$  is BLAKE2b and the non-strings  $p$ ,  $T$ ,  $m$ ,  $t$ ,  $v$ ,  $y$ ,  $\text{length}(P)$ ,  $\text{length}(S)$ ,  $\text{length}(K)$ , and  $\text{length}(X)$  are treated as a 32-bit little-endian encoding of the integer.

$$H_0 = H(p, T, m, t, v, y, \text{length}(P), P, \text{length}(S), S, \text{length}(K), K, \text{length}(X), X)$$

2. Allocate the memory as  $m'$  1024-byte blocks where  $m'$  is derived

as:

$$m' = 4 * p * \text{floor} (m / 4p)$$

For tunable parallelism with  $p$  threads, the memory is organized in a matrix  $B[i][j]$  of blocks with  $p$  rows (lanes) and  $q = m' / p$  columns.

3. Compute  $B[i][0]$  for all  $i$  ranging from (and including) 0 to (not including)  $p$ .

$$B[i][0] = H'(H0, \text{4byteencode}(i), \text{4byteencode}(0))$$

Here `4byteencode` is a function which takes an integer and little-endian encode and pads it to 4 bytes.

4. Compute  $B[i][1]$  for all  $i$  ranging from (and including) 0 to (not including)  $p$ .

$$B[i][1] = H'(H0, \text{4byteencode}(i), \text{4byteencode}(1))$$

5. Compute  $B[i][j]$  for all  $i$  ranging from (and including) 0 to (not including)  $p$ , and for all  $j$  ranging from (and including) 2) to (not including)  $q$ . The block indices  $i'$  and  $j'$  are determined differently for Argon2d and Argon2i.

$$B[i][j] = G(B[i][j-1], B[i'][j'])$$

6. If the number of iterations  $t$  is larger than 1, we repeat the steps however replacing the computations with with the following expression:

$$\begin{aligned} B[i][0] &= G(B[i][q-1], B[i'][j']) \\ B[i][j] &= G(B[i][j-1], B[i'][j']) \end{aligned}$$

7. After  $t$  steps have been iterated, we compute the final block  $C$  as the XOR of the last column:

$$C = B[0][q-1] \text{ XOR } B[1][q-1] \text{ XOR } \dots \text{ XOR } B[p-1][q-1]$$

8. The output tag is computed as  $H'(C)$ .

### 3.3. Variable-length hash function H'

Let  $H_x$  be a hash function with  $x$ -byte output (in our case  $H_x$  is Blake2b, which supports  $x$  between 1 and 64 inclusive). Let  $V_i$  be a 64-byte block, and  $A_i$  be its first 32 bytes, and  $T < 2^{32}$  be the tag length in bytes. Then we define

$$\begin{aligned} V_0 &= T || X \\ V_1 &= H_{64}(V_0) \\ V_2 &= H_{64}(V_1) \\ &\dots \\ V_r &= H_{64}(V_{r-1}) \quad \text{with } r = \text{floor}(T/32) - 1 \\ V_{r+1} &= H_{\{T \bmod 64\}}(V_{r-1}) \quad \text{absent if 64 divides } T \\ H'(X) &= A_1 || A_2 || \dots || A_r || V_{r+1} \end{aligned}$$

FIXME: improve this description. FIXME2:  $V_{r+1}$  is not properly described, is it a 64-byte block or a  $\{T \bmod 64\}$  block?

### 3.4. Indexing

TBD

### 3.5. Compression function G

Compression function  $G$  is built upon the Blake2b round function  $P$ .  $P$  operates on the 128-byte input, which can be viewed as 8 16-byte registers:

$$P(A_0, A_1, \dots, A_7) = (B_0, B_1, \dots, B_7)$$

Compression function  $G(X, Y)$  operates on two 1024-byte blocks  $X$  and  $Y$ . It first computes  $R = X \text{ XOR } Y$ . Then  $R$  is viewed as a  $8 \times 8$ -matrix of 16-byte registers  $R_0, R_1, \dots, R_{63}$ . Then  $P$  is first applied rowwise, and then columnwise to get  $Z$ :

$$\begin{aligned} (Q_0, Q_1, \dots, Q_7) &\leftarrow P(R_0, R_1, \dots, R_7) \\ (Q_8, Q_9, \dots, Q_{15}) &\leftarrow P(R_8, R_9, \dots, R_{15}) \end{aligned}$$

```

...
(Q_56, Q_57, ... , Q_63 ) <- P(R_56, R_57, ... , R_63)
(Z_0, Z_8, Z_16 , ... , Z_56) < P(Q_0, Q_8, Q_16, ... , Q_56)
(Z_1, Z_9, Z_17 , ... , Z_57) < P(Q_1, Q_9, Q_17, ... , Q_57)
...
(Z_7, Z_15, Z_23 , ... , Z_63) < P(Q_7, Q_15, Q_23, ... , Q_63)

```

Finally, G outputs Z XOR R:

G: (X,Y) -> R = X XOR Y -P-> Q -P-> Z -P-> Z XOR R

FIXME: improve this description.

### [3.6.](#) Permutation P

TBD

## [4.](#) Parameter Choice

Argon2d is optimized for settings where the adversary does not get regular access to system memory or CPU, i.e. he can not run side-channel attacks based on the timing information, nor he can recover the password much faster using garbage collection. These settings are more typical for backend servers and cryptocurrency minings. For practice we suggest the following settings:

- o Cryptocurrency mining, that takes 0.1 seconds on a 2 Ghz CPU using 1 core -- Argon2d with 2 lanes and 250 MB of RAM.
- o Backend server authentication, that takes 0.5 seconds on a 2 GHz CPU using 4 cores -- Argon2d with 8 lanes and 4 GB of RAM.

Argon2i is optimized for more realistic settings, where the adversary possibly can access the same machine, use its CPU or mount cold-boot attacks. We use three passes to get rid entirely of the password in the memory. We suggest the following settings:

- o Key derivation for hard-drive encryption, that takes 3 seconds on a 2 GHz CPU using 2 cores - Argon2i with 4 lanes and 6 GB of RAM

- o Frontend server authentication, that takes 0.5 seconds on a 2 GHz CPU using 2 cores - Argon2i with 4 lanes and 1 GB of RAM.

We recommend the following procedure to select the type and the parameters for practical use of Argon2.

1. Select the type  $y$ . If you do not know the difference between them or you consider side-channel attacks as viable threat, choose Argon2i.
2. Figure out the maximum number  $h$  of threads that can be initiated by each call to Argon2.
3. Figure out the maximum amount  $m$  of memory that each call can afford.
4. Figure out the maximum amount  $x$  of time (in seconds) that each call can afford.
5. Select the salt length. 128 bits is sufficient for all applications, but can be reduced to 64 bits in the case of space constraints.
6. Select the tag length. 128 bits is sufficient for most applications, including key derivation. If longer keys are needed, select longer tags.
7. If side-channel attacks is a viable threat, enable the memory wiping option in the library call.
8. Run the scheme of type  $y$ , memory  $m$  and  $h$  lanes and threads, using different number of passes  $t$ . Figure out the maximum  $t$  such that the running time does not exceed  $x$ . If it exceeds  $x$  even for  $t = 1$ , reduce  $m$  accordingly.
9. Hash all the passwords with the just determined values  $m$ ,  $h$ , and  $t$ .

TBD -- is there a python implementation?

## 6. Test Vectors

This section contains test vectors for Argon2.
