Native Short Addressing for Low power and Lossy Networks Expansion
draft-li-6lo-native-short-address-02

Abstract

This document specifies a topological addressing scheme, Native Short Address (NSA) that enables IP packet transmission over links where the transmission of a full length address may not be desirable. This document focuses on carrying IP packets across an LLN (Low power and Lossy Network), in which the topology is relatively static where nodes' location is fixed and the connection between nodes is rather stable. The changes in the logical topology are only caused by non-frequent disconnection in the link. The specifications details the NSA architecture, address allocation, forwarding mechanism, header format design, including length-variable fields, and IPv6 interconnection support.

Status of This Memo

This Internet-Draft is submitted in full conformance with the provisions of [BCP 78](#) and [BCP 79](#).

Internet-Drafts are working documents of the Internet Engineering Task Force (IETF). Note that other groups may also distribute working documents as Internet-Drafts. The list of current Internet-Drafts is at <https://datatracker.ietf.org/drafts/current/>.

Internet-Drafts are draft documents valid for a maximum of six months and may be updated, replaced, or obsoleted by other documents at any time. It is inappropriate to use Internet-Drafts as reference material or to cite them other than as "work in progress."

This Internet-Draft will expire on 5 September 2022.

[1.](#) Introduction

There is an ongoing massive expansion of the network edge that is driven by the "Internet of Things" (IoT), especially over low-power links which often, in the past, did not support IP packet

transmission.

Particularly driven by the requirements stemming from Industry 4.0 and Smart City deployments, more and more devices/things are connected to the Internet. Sensors in plants/parking bays/mines,

temperature/humidity/flash sensors in museums, normally are located in a fixed position and are networked by low power and lossy links even in hardwired networks. Comparing with traditional scenarios, scalability of the (edge) network along with lower power consumption are key technical requirements. Moreover, large-scale Low power Lossy Networks (LLNs) are expected to be able to carry IPv6 packets over their links, together with an efficient access to native IPv6 domains.

The work in [[SIXLOWPAN](#)]/[[SIXLO](#)]/[[LPWAN](#)] Working Groups addresses many fundamental issues for those type of deployments. Those deployments can be considered an instantiation of what [[RFC8799](#)] defines as "limited domains". For instance, the 6lowpan compression technology ([[RFC4944](#)] and [[RFC6282](#)]) addresses the problem of IPv6 transmission over LLNs, making it possible to interconnect IPv6-based IoT networks and the Internet. [[RFC8138](#)] introduces a framework for implementing multi-hop routing on an LLN using a compressed routing header, which works also with RPL (Routing Protocol for LLNs [[RFC6550](#)]). This technique enables the ability to forward IPv6 packets within the domain without the need of decompression. In addition, SCHC (Generic Framework for Static Context Header Compression and Fragmentation [[RFC8724](#)]) enables even more compression by using a common static context.

Although aforementioned technologies are suitable in general for all IoT scenarios, there could be more simplified solutions for those scenarios and applications with static network topology and stable network connections leveraging on wired technologies [[I-D.ietf-6lo-use-cases](#)] (e.g. smart building, smart parking, etc.). In those kinds of deployments, topologies are planned in advance and well provisioned, with sensor nodes usually fixed in specific locations. This draft presents a topology based addressing mechanism with shorter packet header and simpler forwarding rules for those static IoT networks.

Internet-Draft

NSA

March 2022

The specifications in this document leverage on previous work, namely using the dispatch type field ([[RFC4944](#)], [[RFC8025](#)]) that allows to accommodate the proposed address format. This means that except the addresses (source and destination) the other fields of the header will be compressed mostly according to LOWPAN_IPHC. The proposed addressing is independent of Unique Local Addresses [[RFC4193](#)], which has a dependency on specific link-layer conventions [[RFC6282](#)]. It is also different from stateful address allocation that requires all nodes to obtain addresses from a centralized DHCP server, which leads to long network startup time and consumption of extra bandwidth. Compared to RPL-based routing [[RFC6550](#)], NSA avoids the extra overhead of address assignment by integrating address assignment and tree forming together. Furthermore, NSA provides much smaller forwarding table size than storing mode RPL.

[2.](#) Requirements Notation

The key words "MUST", "MUST NOT", "REQUIRED", "SHALL", "SHALL NOT", "SHOULD", "SHOULD NOT", "RECOMMENDED", "NOT RECOMMENDED", "MAY", and "OPTIONAL" in this document are to be interpreted as described in [BCP 14](#) [[RFC2119](#)] and [[RFC8174](#)] when, and only when, they appear in all capitals, as shown here.

[3.](#) Architectural Overview

Native Short Address (NSA) is an efficient topology-based network layer address assignment and packet forwarding mechanism that is performed in a decentralized fashion. The NSA nodes are aware of their own IPv6 address, constructed by IPv6 prefix and the NSA (see

[Section 4.1](#) and [Section 5.2](#)). Inside the NSA domain, nodes communicate with each other using only NSA addresses. It is a smaller address space compared to the huge IPv6 addressing space. The NSA enables stateless forwarding. When IPv6 communication occurs between nodes inside the NSA domain and external IPv6 nodes, the border router, which plays as well the role of "root" in the addressing tree, performs network address translation (as per [Section 5.2](#) and [\[RFC6282\]](#)). The architecture of NSA network is showed in Figure 1.

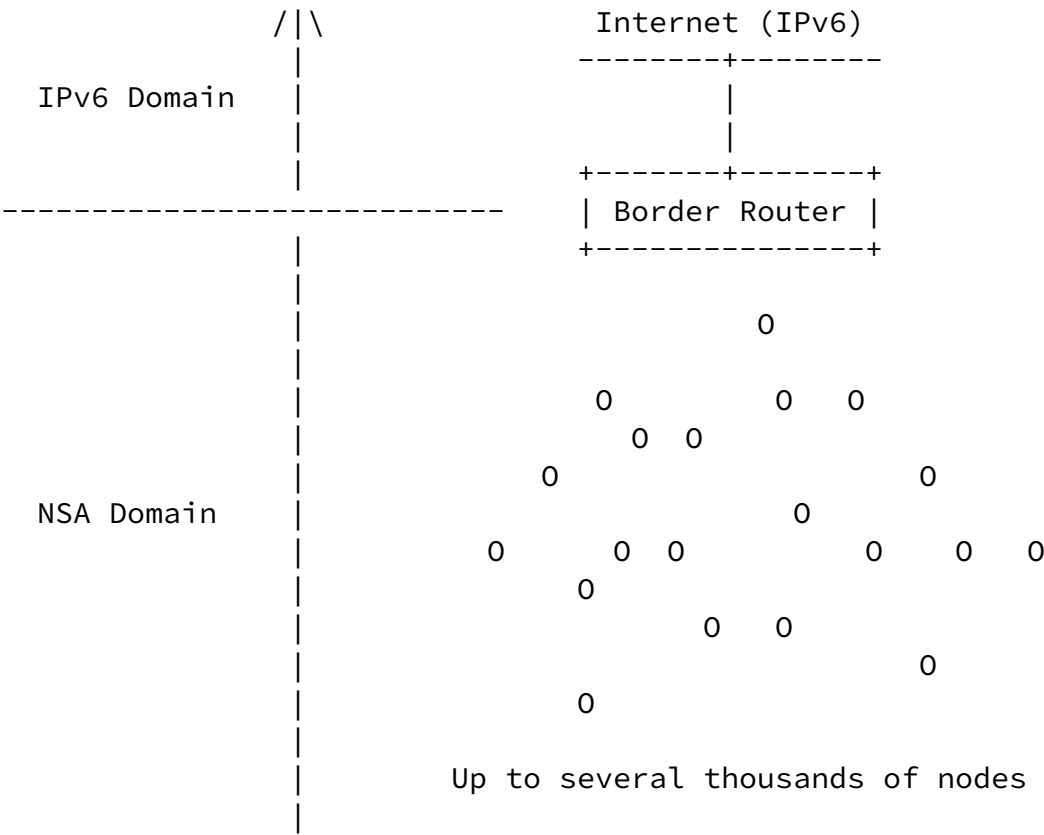

Figure 1: The architecture of general NSA networks.

In the NSA network, there are 3 types of nodes, the root node, the forwarder node and the leaf node. There is typically one root node in the NSA network. The root node is responsible for the management of the whole NSA network and routing/forwarding both internal and external traffic. It stores the IPv6 prefix of the domain in order to perform the network address translation for external communications. It also stores the address Allocation Function (AF) and performs the address assignment for its children. After successful address assignment, the root will keep the state of its children and refresh them when changed. The root node functions as gateway between the NSA domain and the Internet. As such it also operates the translation between NSA header and IPv6 header (cf. [Section 5](#)).

A forwarder node is a node, different from the root node, containing at least one child. The forwarder node is basically the root of a sub-tree and its role is to forward traffic between its parent and its children according to addressing. When handling a packet, if the destination is in its sub-tree, it forwards the packet to the right child, otherwise it simple sends it to its parent.

A leaf node is a node with no children. Its operation is simple since it is either a destination or source of every packet it handles. If it is the source of packets, it simply sends the packets to its parent.

Each node acquiring a native short address needs to send an Address Request (AR) message to its link layer neighbors and wait for the response. In the AR message, the node needs to designate a 'role' value (forwarder or leaf) and the 'node-id'. The latter is a unique identifier of each NSA node, including root, forwarders, and leaves. This document assumes the use of the link-layer address of the node as 'node-id'.

Forwarder and Leaf roles can be assigned similarly to IEEE 802.15.4, which distinguishes between Full-Function Devices (FFD) and reduced

function devices (RFD) (cf., [[ZigBee](#)]). If a neighbor is neither a forwarder nor the root, it will drop the AR message silently. Otherwise, the neighbor will calculate an address based on parameters in the AR message. After the neighbor node assigns an address to the node, using a Allocation function (AF), it stores the suffix of that address as the interface ID towards the node. Then, it generates and sends Address Assignment (AA) message back and becomes the parent node.

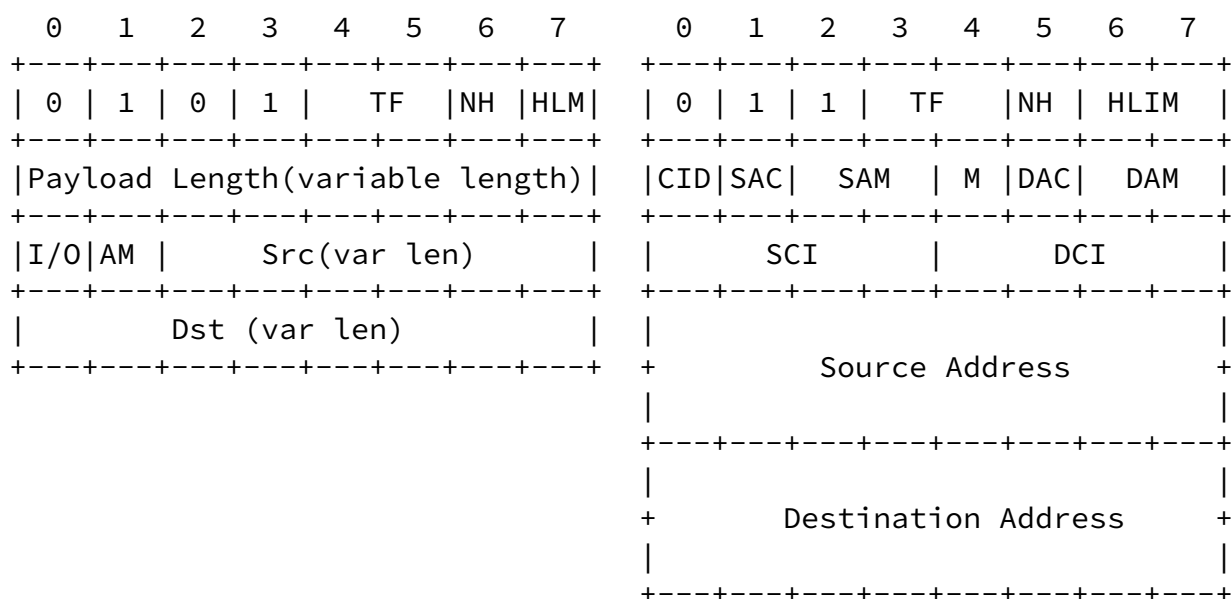

This address assignment relies on the base mechanism described in 6lowpan-ND ([[RFC6775](#)]), but defines two new options of ND message, whose format is defined in [Section 8.2.1](#) and [Section 8.2.2](#).

The acceptance of the address assignment follows "first come first serve" principle. Once a node receives a valid AA response, it uses that assigned address as its own network layer address, thus becomes a child of the address assigner. It will then ignore replies from other neighbors.

If a node does not receive any response after an pre-defined interval, it will send the AR message again. It is RECOMMENDED that nodes re-send the AR message up to 3 times, if no answer is received, they SHOULD stop.

The overall design objective is centered on reducing the size (or completely avoid the usage) of routing/forwarding table with a topological addressing scheme to save communication energy in an IoT LLN network. NSA eliminates compression/decompression of the address and also reduces the amount of information synchronization messages, so it actually reduces computation complexity during packets parsing and forwarding.

To this end, NSA uses a context-independent address encoding mechanism. It does not carry any field about address context in the packet. It carries source and destination addresses by variable length fields whose size can be reduced to one byte each in the best case. This allows the NSA packet header to be smaller than LOWPAN_IPHC's 7 bytes (see Figure 2), down to 4 bytes, representing around 40% reduction in the header size.

a. NSA best case header

b. IPHC best case header
with context-based encoding
and global unicast address

Figure 2: Best case of NSA and LOWPAN_IPHC packet header.

There are three distinct NSA features that allow NSA to be efficient, namely:

1. Native Short Address allocation (see [Section 4](#)),
2. Stateless forwarding (see [Section 5](#)),
3. Compact header format design (see [Section 7](#)) that avoids context and compression.

4. NSA Allocation

The basic rules of allocation include:

- * Each node's address is prefixed by their parent's address.

- * The root/forwarder runs an AF (Allocation Function) to generate

Figure 4: Definition of the Allocation Function (AF) of forwarder/root nodes.

Taking the example of the topology in Figure 3, the proposed AF works as follows.

At the top level, there are 4 children of root, two are forwarders and the other two are leaves. Starting from the left most node and moving to the right, the root node applies the AF as follows:

* For the first child, which is a forwarder:

- $A(\text{'forwarder'}, 0, 0) = \text{'1'}(\text{root address}) + b(0) + \text{'0'} = \text{'1'} + \text{'0'} = 10$
- Index f is increased by one and is now equal 1 ($f=1$)

* For the second child, which is a leaf:

- $A(\text{'leaf'}, 1, 0) = \text{'1'}(\text{root address}) + b(0) + \text{'1'} = \text{'1'} + \text{'0'} + \text{'1'} = 11$
- Index l is increased by one and is now equal 1 ($l=1$)

* For the third child, which is a forwarder:

- $A(\text{'forwarder'}, 1, 1) = \text{'1'}(\text{root address}) + b(1) + \text{'0'} = \text{'1'} + \text{'1'} + \text{'0'} = 110$
- Index f is increased by one and is now equal 2 ($f=2$)

* For the fourth child, which is a leaf:

- $A(\text{'leaf'}, 2, 1) = \text{'1'}(\text{root address}) + b(1) + \text{'1'} = \text{'1'} + \text{'1'} + \text{'1'} = 111$
- Index l is increased by one and is now equal 2 ($l=2$)

The first level addresses have now been assigned. Let's now have a look how the node 10 (the first forwarder child of the root) applies the same Allocation Function. Note that node 10 will use its own ' f ' and ' l ' indexes initialized to 0. Starting again from the left most node, node 10 applies the AF as follows:

* For the first child, which is a forwarder:

- $A(\text{'forwarder'}, 0, 0) = \text{'10'}(\text{node address}) + b(0) + \text{'0'} = \text{'10'} + \text{'0'} = 100$

- Index f is increased by one and is now equal 1 ($f=1$)
- * For the second child, which is a leaf:
 - $A(\text{'leaf'}, 1, 0) = \text{'10'}(\text{node address}) + b(0) + \text{'1'} = \text{'10'} + \text{'1'} = 101$
 - Index l is increased by one and is now equal 1 ($l=1$)
- * For the third child, which is a forwarder:
 - $A(\text{'forwarder'}, 1, 1) = \text{'10'}(\text{node address}) + b(1) + \text{'0'} = \text{'10'} + \text{'1'} + \text{'0'} = 1010$
 - Index f is increased by one and is now equal 2 ($f=2$)
- * For the fourth child, which is a leaf:
 - $A(\text{'leaf'}, 2, 1) = \text{'10'}(\text{node address}) + b(1) + \text{'1'} = \text{'10'} + \text{'1'} + \text{'1'} = 1011$
 - Index l is increased by one and is now equal 2 ($l=2$)

Note how the children of the same parent all have the same prefix (10 in this example). The proposed AF algorithmically assigns addresses to the different nodes without the need to know the topology in advance. However, the largest address of the network will depend on the actual topology. Indeed, the maximum length of an address with the proposed AF grows linearly at each level of the tree with the number of siblings from the same parent. Let's take again the example in Figure 3 and let's assume that the children of node 10 are all leaves, for the largest address we need 2 bits to encode the parent node prefix (10 in this case) to which we need to add a number of '1' equal to the value of the l index which is the number of leaves minus one (because the first leaf has index 0), in this case since there are 4 leaves, the index value is 3 and we add the '111' string, hence the address length would be 6 (2 for the prefix, 3 to encode the 4th leaf address, and one for the final 1 the ends all leaves addresses). In a more formal way the maximum address length

at each level can be calculated as (where Ceiling just returns the least integer greater or equal its argument):

$$\text{Max_Length} = \text{length}(\text{Parent address}) \\ \text{length}(\text{b}(\text{max}(\text{f}, \text{l}))) \\ + 1$$

Where f and l are the indexes counting respectively the forwarders and the leaves at this level.

The Allocation Function can be different from the one defined in Figure 4, but all nodes know which one to use by configuration. The use of one and only one AF is allowed in an NSA domain. It is RECOMMENDED that implementations support at least the AF proposed in this document (cf. [Section 9](#)).

Different allocation function may, for example, leverage on a priori knowledge of the topology in order to optimize the maximum address size and make it smaller. For instance, because the order of address allocation has an impact on the size, the address of children with the largest subtree should be allocated in the first place so to reduce the average address length of the whole subtree. Also, knowing the traffic in advance, or being able to have an estimation, can help to minimize the size of addresses that have a lot of traffic. This kind of optimization can be an option, the specification of optimizations is out of the scope of this document and may be defined in new Allocation Functions to be added to the "Allocation Function Registry" (see [Section 9](#)).

[4.1](#). NSA Addresses and IPv6 Addresses

Obtaining a full IPv6 address from a NSA address is pretty straightforward. First the NSA address is concatenated to the configured IPv6 prefix. Since the length of the NSA address is smaller than or equal to 64 bits (the interface ID length in IPv6), the node needs to pad it with zeros ('0') used as most significant bits. The full IPv6 address will look like: IPv6 prefix + "000...000" + NSA (or in IPv6 notation <IPv6 Prefix>::<NSA>). The NSA is assigned by the root/forwarder as previously described.

In an IPv6 communication, the node will derive the NSA address as the short source address from its own IPv6 address by simply removing the

IPv6 prefix and all leading zeros before the NSA part. The node will compare the destination IPv6 address with its own IPv6 address. If they have the same prefix, it means that the destination is in the local NSA domain and its corresponding NSA address will be extracted as the short destination address (and the I/O Flag can be set accordingly). Otherwise, it will be a communication towards the Internet. In that case, a mapping mechanism implemented on the root node will generate a short address to be mapped to the full IPv6 destination address. For instance, the mapped short address can be generated using the least significative bits of the original IPv6 address. As previously stated, the mapping mechanism is out of the scope of this document.

Since the short mapped address is generated on the root, when the node first open the connection toward the external site, with a first packet, the destination address is set to the full, uncompressed,

IPv6 address. Once the packet arrives to the root node, performing the destination address lookup the root will notice that a full IPv6 address is being used and will trigger the short address generation mechanism and create a new mapping. Such, mapping is communicated to the source node via a new dedicated ICMP message (see [Section 8](#)). Once the node originating the communication receives such a message it SHOULD use the mapped short address for any further communication.

[4.2](#). Limitation of Number of Children Nodes

The maximum number of child nodes is determined by the specific AF used. IEEE 802.15.5 has explored the use of a per-branch setup, which, however, incurs scalability problems [[LEE10](#)]. NSA allocation design is more flexible and extensible than the one proposed in IEEE 802.15.5. The AF used as example in this document does not need any specific setup network by network, though it is still limited by the maximum length of addresses. For the special case of the parent connecting to huge amount of children, a variant of the proposed AF can be designed to fulfill the requirement and optimize the address allocation (as previously described).

[5](#). Forwarding in a NSA Network

Internal and external communications in an NSA network work slightly different. For internal communications, among NSA endpoints, packets

carry native short addresses and no special operation is needed. For external communications, the root is responsible to perform the translation between native short addresses and IPv6 addresses. For instance, for a packet entering into the NSA domain, the root will extract the native short address of the destination from the suffix of the IPv6 address, by removing all leading '0's. It will also map the source IPv6 address to a mapped native short address, in order to make it more efficient for communication inside the NSA domain.

The root has to store the mapping between external IPv6 addresses and their assigned mapped Native Short Addresses. The method of generating those mapping is out of scope of this document, however, the addressing space for the external NSA has to be maintained separate from the internal NSA address space. Overlap are allowed since the two addressing space are distinguishable in the packets by the use of the I/O field, as explained later on.

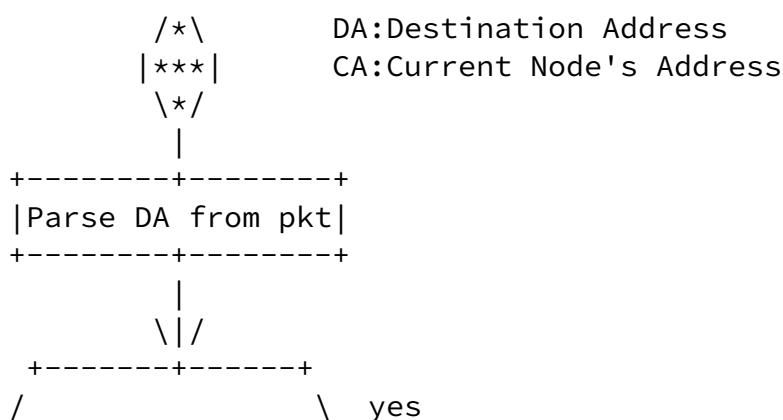

The following paragraphs will detail the forwarding operations for both internal and external communication. The intra-network forwarding procedure depends on the specific AF used. Here we will use the AF previously introduced (see Figure 4) to illustrate the forwarding procedure.

[5.1.](#) Forwarding toward an NSA endpoint

To perform forwarding operations, NSA nodes access the I/O field in the NSA header (see [Section 7](#)). When its value is 1, the packet is destined to an internal NSA node, so it is an inner-domain packet. Otherwise, the packet is destined to an external IPv6 node. It is called an outer-domain packet. Intra-domain packets carry a native short addresses in the source and the destination address fields. More specifically the destination address field is the address of another node in the same NSA domain. As such an NSA node performs the following sequence of actions (also see Figure 5):

1. Get destination address from packet (abbreviated to DA) and the current node's address (abbreviated to CA). Go to step 2.
2. If length of DA is smaller than length of CA, send the packet to parent node, exit. Otherwise, go to step 3.

3. If length of DA equals to length of CA, go to step 4. Otherwise, go to step 5.
4. If DA and CA are the same, the packet arrived at destination, exit. Otherwise, send the packet to parent node, exit.
5. Check whether CA is equal to the prefix of DA. If yes, go to step 6. Otherwise, send the packet to parent node, exit.
6. Calculate which child is the next hop address and forward packet to it. With the AF propose in this document such operation reduces to reading the DA's bits starting from the position equals to the length of CA, then skip all '1' until the first '0' or the last bit of DA. The sub-string obtained in such a way is the address of direct child of current node.
7. If any exception happens in the above steps, drop the packet and send error notification.

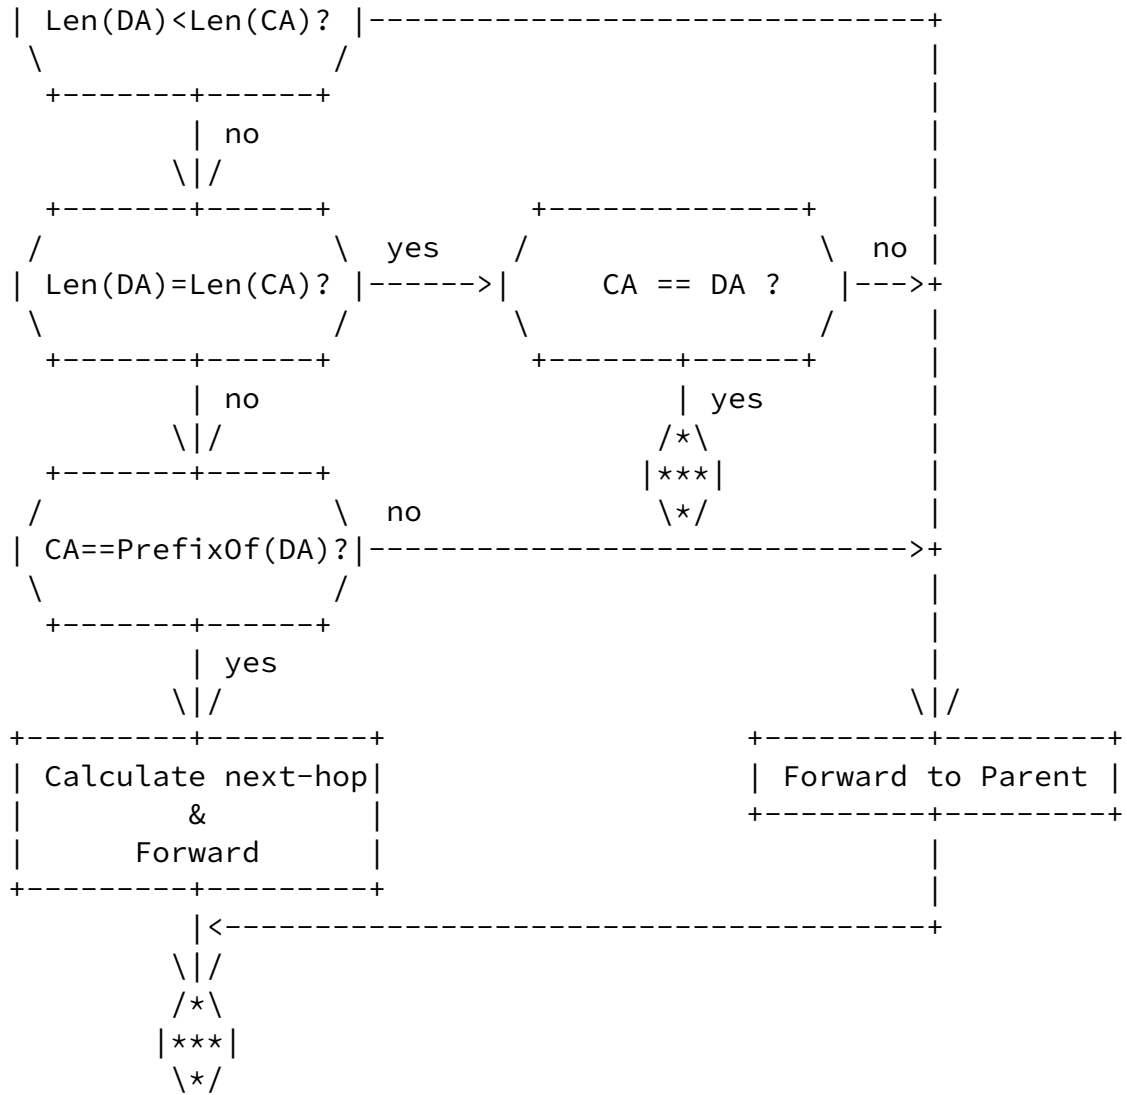

Figure 5: Flow Chart of Internal Forwarding Procedure

In the case of packet arriving from the Internet (external IPv6 domain toward the local NSA domain) header adaptation operation is performed by the root node. Concerning the destination address, the root builds the native short address of the destination by removing the prefix and the leading '0's of the suffix of the destination

address. Meanwhile, it checks whether it exists already a mapping between the source address and a mapped NSA address to be used as source address in the NSA packet. If not it creates one. Then the root creates the inner-domain packet. It uses the NSA address as

destination setting the I/O field to 1 so to route the packet to as described above to the destination node. The mapped NSA address is used as source address and the fact that is a Mapped Address is signaled by setting to 1 the MA field.

[5.2.](#) Forwarding toward an external IPv6 node

In the case that the I/O field (cf. [Section 7](#)) is set to 0, the packet is destined to an external IPv6 node, it is an outer-domain packet. As such the destination address is either a full IPv6 address (for the first packet of a communication) or a mapped short address generated by the root node and not belonging to any node inside the NSA domain.

All NSA nodes (except root) just send packets that are destined outside the local domain (I/O field equal 0) to their parent, not even looking at the actual destination address. Eventually all packets will reach the root node, which acts as gateway. The root node is able to map the destination NSA address to the corresponding full IPv6 address. Also, the root node is able to rebuild the full source IPv6 address by concatenating the IPv6 prefix and the NSA address as explained in [Section 5.2](#). Other fields of the header are also decompressed as described in [Section 7](#). A full IPv6 header replaces the original NSA header in the packet, which is then forwarded according to traditional IPv6 protocol.

[6.](#) Benefits of Native Short Addressing

The NSA use a single set of messages for address assignment and tree forming. It is not more complex than RPL tree forming. So, NSA saves the overhead of address assignment of RPL.

Comparing to RPL with storing mode (see [[RFC6550](#)]), there is no need for a NSA node to generate and store forwarding table entries in the normal case. One of the potential issues is the risk of renumbering of addresses in case of topology changes. Because of the applicability domain of NSA, the common case of topology change is known in advance and can be planned, so to reduce disruption due to renumbering. Another case is temporary link failures where the underlying technology is still able to provide connectivity through alternative links.

In this scenario a node can temporarily "move" along with its whole subtree. Instead of performing a renumbering of the whole subtree, which may cause disruption, the subtree rooted on the "moving" node, its address and the addresses of all its children and grand-children can be kept unchanged, by creating a temporary entry in the forwarding tables of the original and new parent nodes, in order to make the subtree still reachable.

Herewith one example, also depicted in Figure 6, node A with the address of 1000 somehow moves from node B (original parent) to node C (new parent). In this case, the forwarding tables in B, C and their parents' nodes should be updated by adding a new entry to "1000", the address of node A. Meanwhile, the original parent (node B) should keep its original address assignment. Comparing with renumbering the addresses of node A and its children, the cost of adding one new route to their parent nodes is much lower, although in this case, the NSA does not implement complete stateless forwarding. However, this solution SHOULD be used only in case of temporary topology changes, where the entries will be deleted once the original topology is re-established. On top of that, it is RECOMMENDED to perform the re-numbering by running the NSA Allocation Function periodically.

Figure 6: Add extra routes for "logic topology change"

7. NSA Header Format

As explained in [Section 4](#), the addresses in NSA are of variable length, in this section, we outline the design of the header format partially based on the format of 6lowPAN, accommodating the variable length property in the packet. The header format is shown in Figure 7.

Figure 7: Header format of NSA packets

The first 4 bits are new dispatch types that will be introduced in [Section 9](#).

- * TF: The same definition as in [\[RFC6282\] Section 3.1.1](#).
- * NH: The same definition as in [\[RFC6282\] Section 3.1.1](#).
- * HL: This field indicates the hop limit. When HL is 1, a hop limit field defined in [\[RFC2460\]](#) locates in in-line fields, while HL is 0 means no hop limit header in packet.
- * Payload length is a variable length field. It normally occupies an byte assuming most packets are smaller than 252 bytes. For larger packets, payload length may expand to 2 to 3 bytes. The encoding method is defined as follows. When the first byte has value of:
 - 0~252: Indicates how many bytes the payload consist of.
 - 253: Indicates that there is an extra byte for payload length,

with the actual length value equal to the last byte value plus 252.

- 254: Indicates that there is an extra two bytes for payload length, with the actual length value obtained from the second and third bytes interpreted as a 16 bits unsigned integer plus 252 (from the first byte).

- 255: Reserved.
- * I/O: Indicates whether this packet is destined to a inner-domain node (value '1') or an outer-domain node (value '0'), where the former means from an NSA or IPv6 node to a NSA destination, while the latter means to an external IPv6 node.
- * MA: Indicates the source address is actually a Mapped Address generated by the root. When it is '1', the source address of the packet is a mapped address of an external IPv6 address, while if it is '0', the source address of the packet is an NSA address.

For length variable native short address encoding, for both Source Address (SA) and Destination Address (DA), the definition is:

- * 0~252: if the address value locates in this interval, one byte is used to encode the value
- * 253: indicates that the following 2 bytes encode the address.
- * 254: indicates that the following 4 bytes encode the address.
- * 255: indicates that the following byte defines the length of address in bytes, followed by the address bytes.

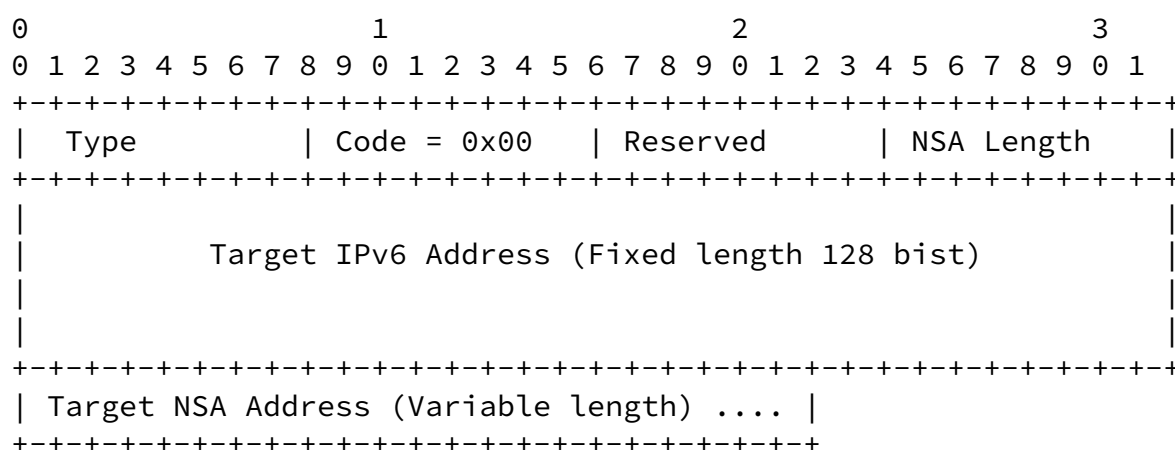

The sequence of in-line fields is as per [\[RFC8200\] section 3](#).

[8](#). NSA Control Message

[8.1](#). New Control Message

This documents specifies only one new NSA Control Message, namely the NSA Mapped Address Advertisement described in [Section 4](#). The purpose

of such a message is advertise the mapping of an IPv6 address into a NSA address. The map is performed by the root node and sent to the node originating the communication. The root keeps a copy of the mapping to be used for future packets. The format is as follows:

- * **Type:** Type value identifying NSA Control Message. Value to be assigned by IANA (cf. [Section 9](#))
- * **Code:** This field identifies the specific control message. In this case it is set to the value 0x00 "NSA Mapped Address for External IPv6 Address".
- * **Reserved:** Set as 0 on transmission and ignored on reception.
- * **NSA Length:** This field indicates the length of the Target NSA Address at the end of the message, expressed in bytes.

The "NSA Mapped Address for External IPv6 Address" is a variable

length message, however, the first five fields of the message, namely Type, Code Reserved, NSA Length, and Target IPv6 address, have a fixed length of 160 bits (20 bytes), hence the length of the NSA address is sufficient to calculate the length of the entire packet: 20 bytes + "NSA length".

8.2. Address Configuration based on 6LOWPAN-ND

According to [[rfc6775](#)], neighbor discovery is available in 6LoWPANs. This document specifies NSA address configuration mechanism based on RS (Router Solicitation) and solicited RA (Router Advertisement) defined in [[RFC4861](#)]. In order for an NSA node to request an address, it uses a newly defined 'Request Address Option (NRAO)' in RS messages. The corresponding solicited RA will contain the 'NSA Assign Address Option (NAAO)' with the assigned address.

8.2.1. NSA Request Address Option (NRAO) Format

This option will be carried in RS messages [[RFC4861](#)] when node initializes. The same RS messages MUST carry the Source Link-Layer Address Option (SLLAO) ([[RFC4861](#)], [[RFC6775](#)]) as well. The link-layer address in SLLAO (Source Link-Layer Address Option) will be used to identify unique NSA node. The NRAO format is defined as follows:

-----+-----+-----+-----
Type Length Expected Address Lifetime
-----+-----+-----+-----
Reserved
-----+-----+-----+-----

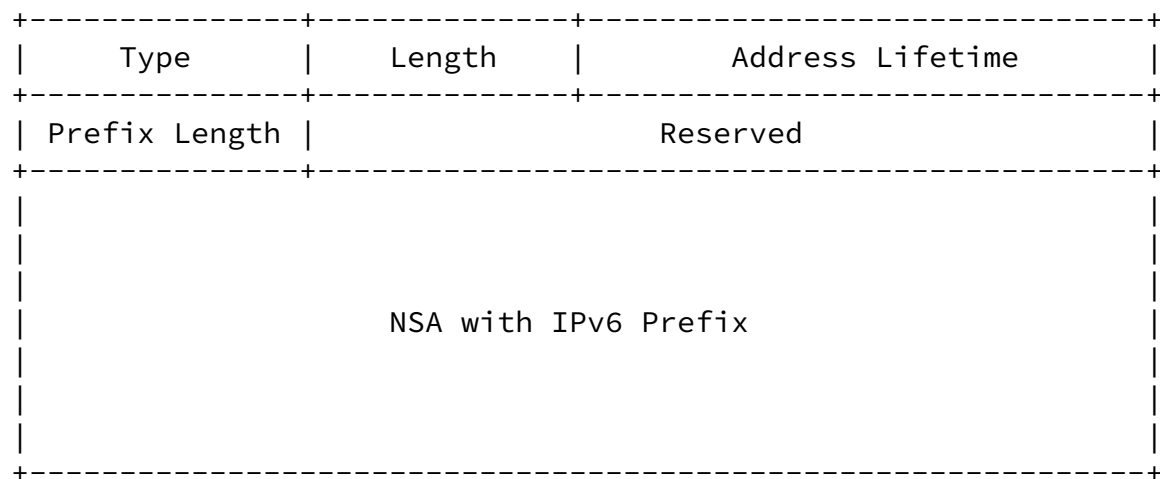

* Type: 136

* Length: 8-bit unsigned integer. The length of the option (including the Type and Length fields) in units of 8 bytes. Be always 1.

- * Expected Address Lifetime: The sender of RS notify the node that assigns the address for how long is expected to be valid. The receiver may ignore this field. The unit is 1 second. This field should be set to zero by sender if there is no requirement on the lifetime.
- * Reserved: These fields are unused. They MUST be initialized to zero by the sender and MUST be ignored by the receiver.

[8.2.2.](#) NSA Assign Address Option (NAAO) Format

This option will be carried in RA message solicited by the an RS message as for the usual Neighbor Discovery workflow. The NAAO format is defined as follows:

- * Type: 137
- * Length: 8-bit unsigned integer. The length of the option (including the Type and Length fields) in units of 8 bytes. Be always 3.
- * Address Lifetime: The maximum seconds for the NSA being valid. The node with this address MUST stop using this address for packet transmission when the life time expires. When the Address Lifetime is zero, the node must drop the address immediately. When the lifetime field is 0xFFFF, the address will be valid forever until the node sends another NAAO to update the lifetime.

- * Prefix Length: This field will notify the receiver the length of the the IPv6 prefix.
- * Reserved: These fields are unused. They MUST be initialized to zero by the sender and MUST be ignored by the receiver.
- * NSA with IPv6 Prefix: This field is filled by the node with the IPv6 prefix (according with the length field), the NSA address as the least significant bit of the IPv6 address, and filling the remaining bits in the middle with zeros.

9. IANA Considerations

9.1. Dispatch Type Field

This document requires IANA to assign the range 01010000 to 01011111 in page 10 of the "Dispatch Type Field" registry as follows:

Bit Pattern	Page	Header Type	Reference
0101TTNH	10	LOWPAN NSA IP(LOWPAN_NIP)	[This Document]

Figure 8: LOWPAN Dispatch Type Field requested allocation

9.2. Allocation Function Registry

This section provides guidance to the Internet Assigned Numbers Authority (IANA) regarding registration of values related to the NSA specification, in accordance with [BCP 26](#) [[RFC8126](#)].

IANA is asked to create a registry named "Native Short Addresses (NSA) Parameters".

Such registry should be populated with a one byte sub registry named "Allocation Function" and used to identify the AF used in a NSA deployment. The sub registry is populated as follows:

+-----+-----+-----+-----+

Value	AF Name	Reference
0x00	Native Allocation Function	[This Document]
0x01-0xFF	Un-assigned	

Values can be assigned by IANA on a "First Come, First Served" basis according to [\[RFC8126\]](#).

9.3. ICMP NSA Control Message

IANA is requested to allocate an ICMPv6 type value from the "ICMPv6 Parameters" registry to be used by "NSA Control Message".

Also IANA is requested to create an "NSA Control Codes" sub registry, for the Code field of the ICMPv6 NSA Control Message.

New codes may be allocated through the "Specification Required" procedure as defined in [\[RFC8126\]](#). The following code is currently defined (the others are to be marked as un-assigned):

Code	Description	Reference
0x00	NSA Mapped Address for External IPv6 Address	[This Document]

9.4. NSA Neighbor Discovery Options

IANA is requested to allocate two values from the "IPv6 Neighbor Discovery Option Formats" registry to be used by NRAO and NAAO.

Code	Description	Reference
136	NSA Request Address Option	[This Document]
137	NSA Assign Address Option	[This Document]

10. Security Considerations

An extended security analysis will be provided in future revision of this document. As of this point we consider that the security considerations of [[RFC4944](#)], [[RFC6282](#)] apply.
