A DANE Record and DNSSEC Authentication Chain Extension for TLS
draft-shore-tls-dnssec-chain-extension-00

Abstract

This draft describes a new TLS extension for transport of a DNS record serialized with the DNSSEC signatures needed to authenticate that record. The intent of this proposal is to allow TLS clients to perform DANE authentication of a TLS server certificate without needing to perform additional DNS record lookups. It will typically not be used for general DNSSEC validation of TLS endpoint names.

Status of This Memo

This Internet-Draft is submitted in full conformance with the provisions of [BCP 78](#) and [BCP 79](#).

Internet-Drafts are working documents of the Internet Engineering Task Force (IETF). Note that other groups may also distribute working documents as Internet-Drafts. The list of current Internet-Drafts is at <http://datatracker.ietf.org/drafts/current/>.

Internet-Drafts are draft documents valid for a maximum of six months and may be updated, replaced, or obsoleted by other documents at any time. It is inappropriate to use Internet-Drafts as reference material or to cite them other than as "work in progress."

This Internet-Draft will expire on December 28, 2015.

[1.](#) Requirements Notation

The key words "MUST", "MUST NOT", "REQUIRED", "SHALL", "SHALL NOT", "SHOULD", "SHOULD NOT", "RECOMMENDED", "MAY", and "OPTIONAL" in this document are to be interpreted as described in [[RFC2119](#)].

[2.](#) Introduction

This draft describes a new TLS [[RFC5246](#)] extension for transport of a DNS record serialized with the DNSSEC signatures [[RFC4034](#)] needed to authenticate that record. The intent of this proposal is to allow TLS clients to perform DANE authentication [[RFC6698](#)] of a TLS server certificate without performing additional DNS record lookups and incurring the associated latency penalty. It also provides the ability to avoid potential problems with TLS clients being unable to look up DANE records because of an interfering or broken middlebox on the path between the endpoint and a DNS server. And lastly, it allows a TLS client to validate DANE records itself without needing access to a validating DNS resolver to which it has a secure connection. It will typically not be used for general DNSSEC

validation of endpoint names, but is more appropriate for validation of DANE records such as TLSA, SMIMEA, etc.

This mechanism is useful for TLS applications that need to address the problems described above, typically web browsers or VoIP and XMPP services. It may not be relevant for many other applications. For example, SMTP MTAs are usually located in data centers, may tolerate extra DNS lookup latency, are on servers where it is easier to provision a validating resolver, and are less likely to experience traffic interference from misconfigured middleboxes. Hence DANE authentication of SMTP MTAs [[DANESMTP](#)] is not likely to gain much advantage from this mechanism.

The extension described here allows a TLS client to request in the client hello message that the DNS validation chain be returned in the (extended) server hello message. If the server is configured for DANE authentication, then it performs the appropriate DNS queries, builds the validation chain, and returns it to the client. The server will usually use a previously cached authentication chain, but it will need to rebuild it periodically as described in [Section 5](#). The client then authenticates the chain using a pre-configured trust anchor.

This specification is based on Adam Langley's original proposal for serializing DNSSEC authentication chains [[AGL](#)] and it incorporates his ideas and some of his text. It modifies his approach by using DNS wire formats and assumes that in implementation, the serialized DNSSEC object will be prepared by a DNS-specific module and the validation actions on serialized DNSSEC will also be carried out by a DNS-specific module. An appendix (empty in the 00 version) provides a Python code example of interfacing with a DNS-specific module.

[3.](#) DNSSEC Authentication Chain Extension

[3.1.](#) Protocol

A client MAY include an extension of type "dnssec_chain" in the (extended) ClientHello. The "extension_data" field of this extension MUST be empty.

Servers receiving a "dnssec_chain" extension in the client hello SHOULD return a serialized authentication chain in the extended ServerHello message, using the format described below. If a server is unable to return a authentication chain, or does not wish to return a authentication chain, it does not include a dnssec_chain extension. As with all TLS extensions, if the server does not support this extension it will not return any authentication chain.

3.2. DNSSEC Authentication Chain Data

The "extension_data" field of the "dnssec_chain" extension represents a sequence of DNS resource record sets, which provide a chain from the DANE record being provided to a trust anchor chosen by the server. The "extension_data" field MUST contain a DNSSEC Authentication Chain encoded in the following form:

```
struct {  
    opaque rrset<0..2^16-1>;  
    opaque rrsig<0..2^16-1>;  
} RRset  
  
RRset AuthenticationChain<0..2^16-1>;
```

Each RRset in the authentication chain encodes an RRset along with a signature on that RRset. The "rrsig" field contains the RDATA for the RRSIG record, defined in [Section 3.1 of RFC 4034](#) [RFC4034]. The "rrset" field contains the covered resource records, in the format defined in [Section 3.1.8.1 of RFC 4034](#) [RFC4034]:

```
signature = sign(RRSIG_RDATA | RR(1) | RR(2)... )  
  
RR(i) = owner | type | class | TTL | RDATA length | RDATA
```

The first RRset in the chain MUST contain the DANE records being presented. The subsequent RRsets MUST be an sequence of DNSKEY and DS RRsets, starting with a DNSKEY RRset. Each RRset MUST authenticate the preceding RRset:

For a DNSKEY RRset, one of the covered DNSKEY RRs MUST be the public key used to verify the previous RRset.

For a DS RRset, the set of key hashes MUST overlap with the preceding set of DNSKEY records.

In addition, a DNSKEY RRset followed by a DS RRset MUST be self-signed, in the sense that its RRSIG MUST verify under one of the keys in the DNSKEY RRSET.

The final RRset in the authentication chain, representing the trust anchor, SHOULD be omitted. In this case, the client MUST verify that the key tag and owner name in the final RRSIG record correspond to a trust anchor.

For example, for an HTTPS server at `www.example.com`, where there are zone cuts at `"com."` and `"example.com."`, we might get the following RRsets:

```
. DNSKEY
com. DS
com. DNSKEY
example.com. DS
example.com. DNSKEY
_443._tcp.www.example.com. TLSA
```

Obviously, an authentication chain will be most compact and easiest to verify if each RRset has a single record, i.e., if there is a single DNSKEY RR and a single DS RR at each step. In addition, as suggested above, keeping zone cuts to a minimum also reduces the length of the authentication chain.

4. Construction of Serialized Authentication Chains

This section describes a possible procedure for the server to use to build the serialized DNSSEC chain.

When the goal is to perform DANE authentication [[RFC6698](#)] of the server's X.509 certificate, the DNS record to be serialized is a TLSA record corresponding to the server's domain name.

The domain name of the server MUST be that included in the TLS Server Name Indication extension [[RFC6066](#)] when present. If the Server Name Indication extension is not present, or if the server does not recognize the provided name and wishes to proceed with the handshake rather than aborting the connection, the server uses the domain name associated with the server IP address that the TLS connection arrives on.

The TLSA record to be queried is constructed by prepending the `_port` and `_transport` labels to the domain name as described in [[RFC6698](#)], where `port` is the port number associated with the TLS server. The `transport` is `"tcp"` for TLS servers, and `"udp"` for DTLS servers.

The components of the authentication chain are built by starting at the trust anchor DNSKEY (usually expected to be the DNS root trust anchor) and its corresponding RRSIG signature record, and then for each intervening zone cut, adding the DS record and DNSKEY RRsets and their RRSIGs, and finally the target TLSA record and RRSIG. (As required above, however, the serialized authentication chain will present the RRsets in the opposite order.)

If the server acts as its own full iterative DNS resolver, it can just build the chain as it performs normal iterative resolution of the target record. If the server uses a recursive resolver, it employs a slightly modified lookup algorithm, starting at the trust anchor, prepending additional labels, and looking for NS, DS, and DNSKEY records, until it reaches the target name.

In order to meet the formatting requirements above, the server must perform some pre-processing on the resource records it receives. It must first compute the uncompressed representation of the RRs, removing DNS name compression [[RFC1035](#)] if present. It then extracts the relevant fields from the resource records and assembles them into an RRset.

5. Caching and Regeneration of the Authentication Chain

DNS records have Time To Live (TTL) parameters, and DNSSEC signatures have validity periods (specifically signature expiration times). After the TLS server constructs the serialized authentication chain, it can cache and reuse it in multiple TLS connection handshakes. However, it should keep track of the TTLs and signature validity periods and requery the records and rebuild the authentication chain as needed. A server implementation could carefully track these parameters and requery the chain correspondingly. Alternatively, it could be configured to rebuild the chain at some predefined periodic intervals.

6. Verification

A TLS client making use of this specification, and which receives a DNSSEC authentication chain extension from a server, SHOULD use this information to perform DANE authentication of the server certificate. In order to do this, it uses the mechanism specified by the DNSSEC protocol [[RFC4035](#)]. This mechanism is sometimes implemented in a DNSSEC validation engine or library.

If the record is correctly authenticated, the client then performs DANE authentication according to the DANE TLS protocol [[RFC6698](#)].

7. Trust Anchor Maintenance

The trust anchor may change periodically, e.g. due to a key rollover event by the operator of the initial zone. Managed key rollovers typically use a process that can be tracked by verifiers allowing them to automatically update their trust anchors, as described in [[RFC5011](#)]. TLS clients using this specification are also expected to use such a mechanism to keep their trust anchors updated. Some operating systems may have a system-wide service to maintain and keep

up-to-date the root trust anchor. It may be possible for the TLS client application to simply reference that as its trust anchor, periodically checking whether it has changed.

8. Security Considerations

The security considerations of the normatively referenced RFCs (1035, 4034, 4035, 5246, 6066, 6698) all pertain to this extension. As mentioned above, there are particular security pitfalls in creating and using this serialization because it has very different temporal qualities from the usual certificate that would be validated. So the requirements in [Section 6](#) ([Section 5](#)) for not caching and for maintaining very good clock synchronization on the client are quite important for avoiding risks of replay or of use of revoked certificates. Other residual risks of this specification include locating the validation function in the server rather than in the client. This might seem reasonable on the face of it, but because the DNSSEC serialization is sent in the clear in the client hello, it could be tampered with and the certificate fingerprint or full certificate (depending on the mode) should not be used without performing the DNSSEC validation (in the DNS-specific module).

DNSSEC signatures have validity periods defined by an inception and expiration time. TLS clients need roughly accurate time in order to properly authenticate these signatures. This could be achieved by running a time synchronization protocol like NTP [[RFC5905](#)] or SNTP [[RFC4330](#)], which are already widely used today.

9. IANA Considerations

This extension requires the registration of a new value in the TLS ExtensionsType registry. The value requested from IANA is 53. If the draft is adopted by the WG, the authors expect to make an early allocation request as specified in [[RFC7120](#)].

10. Acknowledgments

Many thanks to Adam Langley for laying the groundwork for this extension. The original idea is his but our acknowledgment in no way implies his endorsement. This document also benefited from discussions with and review from the following people: Allison Mankin, Duane Wessels, Willem Toorop, Jeff Hodges, and Gowri Visweswaran.
