TCP Control Block Interdependence
draft-ietf-tcpm-2140bis-11.txt

Status of this Memo

This Internet-Draft is submitted in full conformance with the provisions of BCP 78 and BCP 79.

This document may contain material from IETF Documents or IETF Contributions published or made publicly available before November 10, 2008. The person(s) controlling the copyright in some of this material may not have granted the IETF Trust the right to allow modifications of such material outside the IETF Standards Process. Without obtaining an adequate license from the person(s) controlling the copyright in such materials, this document may not be modified outside the IETF Standards Process, and derivative works of it may not be created outside the IETF Standards Process, except to format it for publication as an RFC or to translate it into languages other than English.

Internet-Drafts are working documents of the Internet Engineering Task Force (IETF), its areas, and its working groups. Note that other groups may also distribute working documents as Internet-Drafts.

Internet-Drafts are draft documents valid for a maximum of six months and may be updated, replaced, or obsoleted by other documents at any time. It is inappropriate to use Internet-Drafts as reference material or to cite them other than as "work in progress."

The list of current Internet-Drafts can be accessed at
<http://www.ietf.org/ietf/lid-abstracts.txt>

The list of Internet-Draft Shadow Directories can be accessed at
<http://www.ietf.org/shadow.html>

This Internet-Draft will expire on October 12, 2021.

Abstract

This memo provides guidance to TCP implementers that is intended to help improve connection convergence to steady-state operation without affecting interoperability. It updates and replaces RFC 2140's description of sharing TCP state, as typically represented in TCP Control Blocks, among similar concurrent or consecutive connections.

1. Introduction

TCP is a connection-oriented reliable transport protocol layered over IP [RFC793]. Each TCP connection maintains state, usually in a data structure called the TCP Control Block (TCB). The TCB contains information about the connection state, its associated local process, and feedback parameters about the connection's transmission properties. As originally specified and usually implemented, most TCB information is maintained on a per-connection basis. Some implementations share certain TCB information across connections to the same host [RFC2140]. Such sharing is intended to lead to better overall transient performance, especially for numerous short-lived and simultaneous connections, as can be used in the World-Wide Web and other applications [Be94][Br02]. This sharing of state is intended to help TCP connections converge to long term behavior (assuming stable application load, i.e., so-called "steady-state") more quickly without affecting TCP interoperability.

This document updates RFC 2140's discussion of TCB state sharing and provides a complete replacement for that document. This state sharing affects only TCB initialization [RFC2140] and thus has no effect on the long-term behavior of TCP after a connection has been established nor on interoperability. Path information shared across SYN destination port numbers assumes that TCP segments having the same host-pair experience the same path properties, i.e., that traffic is not routed differently based on port numbers or other connection parameters (also addressed further in Section 8.1). The observations about TCB sharing in this document apply similarly to

any protocol with congestion state, including SCTP [RFC4960] and DCCP [RFC4340], as well as for individual subflows in Multipath TCP [RFC8684].

2. Conventions Used in This Document

The key words "MUST", "MUST NOT", "REQUIRED", "SHALL", "SHALL NOT", "SHOULD", "SHOULD NOT", "RECOMMENDED", "NOT RECOMMENDED", "MAY", and "OPTIONAL" in this document are to be interpreted as described in BCP 14 [RFC2119] [RFC8174] when, and only when, they appear in all capitals, as shown here.

The core of this document describes behavior that is already permitted by TCP standards. As a result, it provides informative guidance but does not use normative language, except when quoting other documents. Normative language is used in Appendix C as examples of requirements for future consideration.

3. Terminology

The following terminology is used frequently in this document. Items preceded with a "+" may be part of the state maintained as TCP connection state in the associated connections TCB and are the focus of sharing as described in this document. Note that terms are used as originally introduced where possible; in some cases, direction is indicated with a suffix (_S for send, _R for receive) and in other cases spelled out (sendcwnd).

+cwnd - TCP congestion window size [RFC5681]

host - a source or sink of TCP segments associated with a single IP address

host-pair - a pair of hosts and their corresponding IP addresses

+MMS_R - maximum message size that can be received, the largest received transport payload of an IP datagram [RFC1122]

+MMS_S - maximum message size that can be sent, the largest transmitted transport payload of an IP datagram [RFC1122]

path - an Internet path between the IP addresses of two hosts

PCB - protocol control block, the data associated with a protocol as maintained by an endpoint; a TCP PCB is called a TCB

PLPMTUD - packetization-layer path MTU discovery, a mechanism that uses transport packets to discover the PMTU [RFC4821]

+PMTU - largest IP datagram that can traverse a path [RFC1191][RFC8201]

PMTUD - path-layer MTU discovery, a mechanism that relies on ICMP error messages to discover the PMTU [RFC1191][RFC8201]

+RTT - round-trip time of a TCP packet exchange [RFC793]

+RTTVAR - variation of round-trip times of a TCP packet exchange [RFC6298]

+rwnd - TCP receive window size [RFC5681]

+sendcwnd - TCP send-side congestion window (cwnd) size [RFC5681]

+sendMSS - TCP maximum segment size, a value transmitted in a TCP option that represents the largest TCP user data payload that can be received [RFC6691]

+sssthresh - TCP slow-start threshold [RFC5681]

TCB - TCP Control Block, the data associated with a TCP connection as maintained by an endpoint

TCP-AO - TCP Authentication Option [RFC5925]

TFO - TCP Fast Open option [RFC7413]

+TFO_cookie - TCP Fast Open cookie, state that is used as part of the TFO mechanism, when TFO is supported [RFC7413]

+TFO_failure - an indication of when TFO option negotiation failed, when TFO is supported

+TFOinfo - information cached when a TFO connection is established, which includes the TFO_cookie [RFC7413]

4. The TCP Control Block (TCB)

A TCB describes the data associated with each connection, i.e., with each association of a pair of applications across the network. The TCB contains at least the following information [RFC793]:

- Local process state
 - pointers to send and receive buffers
 - pointers to retransmission queue and current segment
 - pointers to Internet Protocol (IP) PCB
- Per-connection shared state
 - macro-state
 - connection state
 - timers
 - flags
 - local and remote host numbers and ports
 - TCP option state
 - micro-state
 - send and receive window state (size*, current number)
 - congestion window size (sendcwnd)*
 - congestion window size threshold (sssthresh)*
 - max window size seen*
 - sendMSS#
 - MMS_S#
 - MMS_R#
 - PMTU#
 - round-trip time and its variation#

The per-connection information is shown as split into macro-state and micro-state, terminology borrowed from [Co91]. Macro-state describes the protocol for establishing the initial shared state about the connection; we include the endpoint numbers and components (timers, flags) required upon commencement that are later used to help maintain that state. Micro-state describes the protocol after a connection has been established, to maintain the reliability and congestion control of the data transferred in the connection.

We distinguish two other classes of shared micro-state that are associated more with host-pairs than with application pairs. One class is clearly host-pair dependent (shown above as "#", e.g., sendMSS, MMS_R, MMS_S, PMTU, RTT), because these parameters are defined by the endpoint or endpoint pair (sendMSS, MMS_R, MMS_S, RTT) or are already cached and shared on that basis (PMTU [RFC1191][RFC4821]). The other is host-pair dependent in its aggregate (shown above as "*", e.g., congestion window information, current window sizes, etc.) because they depend on the total capacity between the two endpoints.

Not all of the TCB state is necessarily sharable. In particular, some TCP options are negotiated only upon request by the application layer, so their use may not be correlated across connections. Other options negotiate connection-specific parameters, which are similarly not shareable. These are discussed further in Appendix B.

Finally, we exclude `rwnd` from further discussion because its value should depend on the send window size, so it is already addressed by send window sharing and is not independently affected by sharing.

5. TCB Interdependence

There are two cases of TCB interdependence. Temporal sharing occurs when the TCB of an earlier (now CLOSED) connection to a host is used to initialize some parameters of a new connection to that same host, i.e., in sequence. Ensemble sharing occurs when a currently active connection to a host is used to initialize another (concurrent) connection to that host.

6. Temporal Sharing

The TCB data cache is accessed in two ways: it is read to initialize new TCBs and written when more current per-host state is available.

6.1. Initialization of a new TCB

TCBs for new connections can be initialized using cached context from past connections as follows:

TEMPORAL SHARING - TCB Initialization

Cached TCB	New TCB
old_MMS_S	old_MMS_S or not cached*
old_MMS_R	old_MMS_R or not cached*
old_sendMSS	old_sendMSS
old_PMTU	old_PMTU+
old_RTT	old_RTT
old_RTTVAR	old_RTTVAR
old_option	(option specific)
old_ssthresh	old_ssthresh
old_sendcwnd	old_sendcwnd

+Note that PMTU is cached at the IP layer [RFC1191][RFC4821].

*Note that some values are not cached when they are computed locally (MMS_R) or indicated in the connection itself (MMS_S in the SYN).

The table below gives an overview of option-specific information that can be shared. Additional information on some specific TCP options and sharing is provided in Appendix B.

TEMPORAL SHARING - Option Info Initialization

Cached	New
old_TFO_cookie	old_TFO_cookie
old_TFO_failure	old_TFO_failure

6.2. Updates to the TCB cache

During a connection, the TCB cache can be updated based on events of current connections and their TCBS as they progress over time, as shown below:

TEMPORAL SHARING - Cache Updates

Cached TCB	Current TCB	when?	New Cached TCB
old_MMS_S	curr_MMS_S	OPEN	curr_MMS_S
old_MMS_R	curr_MMS_R	OPEN	curr_MMS_R
old_sendMSS	curr_sendMSS	MSSopt	curr_sendMSS
old_PMTU	curr_PMTU	PMTUD+ / PLPMTUD+	curr_PMTU
old_RTT	curr_RTT	CLOSE	merge(curr,old)
old_RTTVAR	curr_RTTVAR	CLOSE	merge(curr,old)
old_option	curr_option	ESTAB	(depends on option)
old_ssthresh	curr_ssthresh	CLOSE	merge(curr,old)
old_sendcwnd	curr_sendcwnd	CLOSE	merge(curr,old)

+Note that PMTU is cached at the IP layer [RFC1191][RFC4821].

Merge() is the function that combines the current and previous (old) values and may vary for each parameter of the TCB cache. The particular function is not specified in this document; examples include windowed averages (mean of the past N values, for some N) and exponential decay ($\text{new} = (1-\alpha) \cdot \text{old} + \alpha \cdot \text{new}$, where α is in the range [0..1]).

The table below gives an overview of option-specific information that can be similarly shared. The TFO cookie is maintained until the client explicitly requests it be updated as a separate event.

TEMPORAL SHARING - Option Info Updates

Cached	Current	when?	New Cached
old_TFO_cookie	old_TFO_cookie	ESTAB	old_TFO_cookie
old_TFO_failure	old_TFO_failure	ESTAB	old_TFO_failure

6.3. Discussion

As noted, there is no particular benefit to caching MMS_S and MMS_R as these are reported by the local IP stack. Caching sendMSS and PMTU is trivial; reported values are cached (PMTU at the IP layer), and the most recent values are used. The cache is updated when the MSS option is received in a SYN or after PMTUD (i.e., when an ICMPv4 Fragmentation Needed [RFC1191] or ICMPv6 Packet Too Big message is received [RFC8201] or the equivalent is inferred, e.g., as from PLPMTUD [RFC4821]), respectively, so the cache always has the most recent values from any connection. For sendMSS, the cache is consulted only at connection establishment and not otherwise updated, which means that MSS options do not affect current connections. The default sendMSS is never saved; only reported MSS values update the cache, so an explicit override is required to reduce the sendMSS. Cached sendMSS affects only data sent in the SYN segment, i.e., during client connection initiation or during simultaneous open; all other segment MSS are based on the value updated as included in the SYN.

RTT values are updated by formulae that merges the old and new values, as noted in Section 6.2. Dynamic RTT estimation requires a sequence of RTT measurements. As a result, the cached RTT (and its variation) is an average of its previous value with the contents of the currently active TCB for that host, when a TCB is closed. RTT values are updated only when a connection is closed. The method for merging old and current values needs to attempt to reduce the transient effects of the new connections.

The updates for RTT, RTTVAR and ssthresh rely on existing information, i.e., old values. Should no such values exist, the current values are cached instead.

TCP options are copied or merged depending on the details of each option. E.g., TFO state is updated when a connection is established and read before establishing a new connection.

Sections 8 and 9 discuss compatibility issues and implications of sharing the specific information listed above. Section 10 gives an overview of known implementations.

Most cached TCB values are updated when a connection closes. The exceptions are MMS_R and MMS_S, which are reported by IP [RFC1122], PMTU which is updated after Path MTU Discovery and also reported by IP [RFC1191][RFC4821][RFC8201], and sendMSS, which is updated if the MSS option is received in the TCP SYN header.

Sharing sendMSS information affects only data in the SYN of the next connection, because sendMSS information is typically included in most TCP SYN segments. Caching PMTU can accelerate the efficiency of PMTUD but can also result in black-holing until corrected if in error. Caching MSS_R and MSS_S may be of little direct value as they are reported by the local IP stack anyway.

The way in which other TCP option state can be shared depends on the details of that option. E.g., TFO state includes the TCP Fast Open Cookie [RFC7413] or, in case TFO fails, a negative TCP Fast Open response. RFC 7413 states, "The client MUST cache negative responses from the server in order to avoid potential connection failures. Negative responses include the server not acknowledging the data in the SYN, ICMP error messages, and (most importantly) no response (SYN-ACK) from the server at all, i.e., connection timeout." [RFC 7413]. TFOinfo is cached when a connection is established.

Other TCP option state might not be as readily cached. E.g., TCP-AO [RFC5925] success or failure between a host pair for a single SYN destination port might be usefully cached. TCP-AO success or failure to other SYN destination ports on that host pair is never useful to cache because TCP-AO security parameters can vary per service.

7. Ensemble Sharing

Sharing cached TCB data across concurrent connections requires attention to the aggregate nature of some of the shared state. For example, although MSS and RTT values can be shared by copying, it may not be appropriate to simply copy congestion window or ssthresh information; instead, the new values can be a function (f) of the cumulative values and the number of connections (N).

7.1. Initialization of a new TCB

TCBs for new connections can be initialized using cached context from concurrent connections as follows:

ENSEMBLE SHARING - TCB Initialization

Cached TCB	New TCB
old_MMS_S	old_MMS_S
old_MMS_R	old_MMS_R
old_sendMSS	old_sendMSS
old_PMTU	old_PMTU+
old_RTT	old_RTT
old_RTTVAR	old_RTTVAR
sum(old_ssthresh)	f(sum(old_ssthresh), N)
sum(old_sendcwnd)	f(sum(old_sendcwnd), N)
old_option	(option specific)

+Note that PMTU is cached at the IP layer [RFC1191][RFC4821].

In the table, the cached sum() is a total across all active connections because these parameters act in aggregate; similarly f() is a function that updates that sum based on the new connection's values, represented as "N".

The table below gives an overview of option-specific information that can be similarly shared. Again, The TFO_cookie is updated upon explicit client request, which is a separate event.

ENSEMBLE SHARING - Option Info Initialization

Cached	New
old_TFO_cookie	old_TFO_cookie
old_TFO_failure	old_TFO_failure

7.2. Updates to the TCB cache

During a connection, the TCB cache can be updated based on changes to concurrent connections and their TCBs, as shown below:

ENSEMBLE SHARING - Cache Updates

Cached TCB	Current TCB	when?	New Cached TCB
old_MMS_S	curr_MMS_S	OPEN	curr_MMS_S
old_MMS_R	curr_MMS_R	OPEN	curr_MMS_R
old_sendMSS	curr_sendMSS	MSSopt	curr_sendMSS
old_PMTU	curr_PMTU	PMTUD+ / PLPMTUD+	curr_PMTU
old_RTT	curr_RTT	update	rtt_update(old, curr)
old_RTTVAR	curr_RTTVAR	update	rtt_update(old, curr)
old_ssthresh	curr_ssthresh	update	adjust sum as appropriate
old_sendcwnd	curr_sendcwnd	update	adjust sum as appropriate
old_option	curr_option	(depends)	(option specific)

+Note that the PMTU is cached at the IP layer [RFC1191][RFC4821].

In the table, rtt_update() is the function used to combine old and current values, e.g., as a windowed average or exponentially decayed average.

The table below gives an overview of option-specific information that can be similarly shared.

ENSEMBLE SHARING - Option Info Updates

Cached	Current	when?	New Cached
old_TFO_cookie	old_TFO_cookie	ESTAB	old_TFO_cookie
old_TFO_failure	old_TFO_failure	ESTAB	old_TFO_failure

7.3. Discussion

For ensemble sharing, TCB information should be cached as early as possible, sometimes before a connection is closed. Otherwise, opening multiple concurrent connections may not result in TCB data sharing if no connection closes before others open. The amount of work involved in updating the aggregate average should be minimized,

but the resulting value should be equivalent to having all values measured within a single connection. The function "rtt_update" in the ensemble sharing table indicates this operation, which occurs whenever the RTT would have been updated in the individual TCP connection. As a result, the cache contains the shared RTT variables, which no longer need to reside in the TCB.

Congestion window size and ssthresh aggregation are more complicated in the concurrent case. When there is an ensemble of connections, we need to decide how that ensemble would have shared these variables, in order to derive initial values for new TCBs.

Sections 8 and 9 discuss compatibility issues and implications of sharing the specific information listed above.

There are several ways to initialize the congestion window in a new TCB among an ensemble of current connections to a host. Current TCP implementations initialize it to four segments as standard [RFC3390] and 10 segments experimentally [RFC6928]. These approaches assume that new connections should behave as conservatively as possible. The algorithm described in [Bal2] adjusts the initial cwnd depending on the cwnd values of ongoing connections. It is also possible to use sharing mechanisms over long timescales to adapt TCP's initial window automatically, as described further in Appendix C.

8. Issues with TCB information sharing

Here, we discuss various types of problems that may arise with TCB information sharing.

For the congestion and current window information, the initial values computed by TCB interdependence may not be consistent with the long-term aggregate behavior of a set of concurrent connections between the same endpoints. Under conventional TCP congestion control, if the congestion window of a single existing connection has converged to 40 segments, two newly joining concurrent connections assume initial windows of 10 segments [RFC6928], and the current connection's window doesn't decrease to accommodate this additional load and connections can mutually interfere. One example of this is seen on low-bandwidth, high-delay links, where concurrent connections supporting Web traffic can collide because their initial windows were too large, even when set at one segment.

The authors of [Hul2] recommend caching ssthresh for temporal sharing only when flows are long. Some studies suggest that sharing ssthresh between short flows can deteriorate the performance of

individual connections [Hul2, Dul6], although this may benefit aggregate network performance.

8.1. Traversing the same network path

TCP is sometimes used in situations where packets of the same host-pair do not always take the same path, such as when connection-specific parameters are used for routing (e.g., for load balancing). Multipath routing that relies on examining transport headers, such as ECMP and LAG [RFC7424], may not result in repeatable path selection when TCP segments are encapsulated, encrypted, or altered - for example, in some Virtual Private Network (VPN) tunnels that rely on proprietary encapsulation. Similarly, such approaches cannot operate deterministically when the TCP header is encrypted, e.g., when using IPsec ESP (although TCB interdependence among the entire set sharing the same endpoint IP addresses should work without problems when the TCP header is encrypted). Measures to increase the probability that connections use the same path could be applied: e.g., the connections could be given the same IPv6 flow label [RFC6437]. TCB interdependence can also be extended to sets of host IP address pairs that share the same network path conditions, such as when a group of addresses is on the same LAN (see Section 9).

Traversing the same path is not important for host-specific information such as `rwnd` and TCP option state, such as `TFOinfo`, or for information that is already cached per-host, such as path MTU. When TCB information is shared across different SYN destination ports, path-related information can be incorrect; however, the impact of this error is potentially diminished if (as discussed here) TCB sharing affects only the transient event of a connection start or if TCB information is shared only within connections to the same SYN destination port.

In case of Temporal Sharing, TCB information could also become invalid over time, i.e., indicating that although the path remains the same, path properties have changed. Because this is similar to the case when a connection becomes idle, mechanisms that address idle TCP connections (e.g., [RFC7661]) could also be applied to TCB cache management, especially when TCP Fast Open is used [RFC7413].

8.2. State dependence

There may be additional considerations to the way in which TCB interdependence rebalances congestion feedback among the current connections, e.g., it may be appropriate to consider the impact of a connection being in Fast Recovery [RFC5681] or some other similar

unusual feedback state, e.g., as inhibiting or affecting the calculations described herein.

8.3. Problems with sharing based on IP address

It can be wrong to share TCB information between TCP connections on the same host as identified by the IP address if an IP address is assigned to a new host (e.g., IP address spinning, as is used by ISPs to inhibit running servers). It can be wrong if Network Address (and Port) Translation (NA(P)T) [RFC2663] or any other IP sharing mechanism is used. Such mechanisms are less likely to be used with IPv6. Other methods to identify a host could also be considered to make correct TCB sharing more likely. Moreover, some TCB information is about dominant path properties rather than the specific host. IP addresses may differ, yet the relevant part of the path may be the same.

9. Implications

There are several implications to incorporating TCB interdependence in TCP implementations. First, it may reduce the need for application-layer multiplexing for performance enhancement [RFC7231]. Protocols like HTTP/2 [RFC7540] avoid connection reestablishment costs by serializing or multiplexing a set of per-host connections across a single TCP connection. This avoids TCP's per-connection OPEN handshake and also avoids recomputing the MSS, RTT, and congestion window values. By avoiding the so-called "slow-start restart", performance can be optimized [Hu01]. TCB interdependence can provide the "slow-start restart avoidance" of multiplexing, without requiring a multiplexing mechanism at the application layer.

Like the initial version of this document [RFC2140], this update's approach to TCB interdependence focuses on sharing a set of TCBs by updating the TCB state to reduce the impact of transients when connections begin, end, or otherwise significantly change state. Other mechanisms have since been proposed to continuously share information between all ongoing communication (including connectionless protocols), updating the congestion state during any congestion-related event (e.g., timeout, loss confirmation, etc.) [RFC3124]. By dealing exclusively with transients, the approach in this document is more likely to exhibit the "steady-state" behavior as unmodified, independent TCP connections.

9.1. Layering

TCB interdependence pushes some of the TCP implementation from the traditional transport layer (in the ISO model), to the network layer. This acknowledges that some state is in fact per-host-pair or can be per-path as indicated solely by that host-pair. Transport protocols typically manage per-application-pair associations (per stream), and network protocols manage per-host-pair and path associations (routing). Round-trip time, MSS, and congestion information could be more appropriately handled at the network layer, aggregated among concurrent connections, and shared across connection instances [RFC3124].

An earlier version of RTT sharing suggested implementing RTT state at the IP layer, rather than at the TCP layer. Our observations describe sharing state among TCP connections, which avoids some of the difficulties in an IP-layer solution. One such problem of an IP layer solution is determining the correspondence between packet exchanges using IP header information alone, where such correspondence is needed to compute RTT. Because TCB sharing computes RTTs inside the TCP layer using TCP header information, it can be implemented more directly and simply than at the IP layer. This is a case where information should be computed at the transport layer but could be shared at the network layer.

9.2. Other possibilities

Per-host-pair associations are not the limit of these techniques. It is possible that TCBs could be similarly shared between hosts on a subnet or within a cluster, because the predominant path can be subnet-subnet, rather than host-host. Additionally, TCB interdependence can be applied to any protocol with congestion state, including SCTP [RFC4960] and DCCP [RFC4340], as well as for individual subflows in Multipath TCP [RFC8684].

There may be other information that can be shared between concurrent connections. For example, knowing that another connection has just tried to expand its window size and failed, a connection may not attempt to do the same for some period. The idea is that existing TCP implementations infer the behavior of all competing connections, including those within the same host or subnet. One possible optimization is to make that implicit feedback explicit, via extended information associated with the endpoint IP address and its TCP implementation, rather than per-connection state in the TCB.

This document focuses on sharing TCB information at connection initialization. Subsequent to RFC 2140, there have been numerous

approaches that attempt to coordinate ongoing state across concurrent connections, both within TCP and other congestion-reactive protocols, which are summarized in [Is18]. These approaches are more complex to implement and their comparison to steady-state TCP equivalence can be more difficult to establish, sometimes intentionally (i.e., they sometimes intend to provide a different kind of "fairness" than emerges from TCP operation).

10. Implementation Observations

The observation that some TCB state is host-pair specific rather than application-pair dependent is not new and is a common engineering decision in layered protocol implementations. Although now deprecated, T/TCP [RFC1644] was the first to propose using caches in order to maintain TCB states (see Appendix A).

The table below describes the current implementation status for TCB temporal sharing in Windows as of December 2020, Apple variants (macOS, iOS, iPadOS, tvOS, watchOS) as of January 2021, Linux kernel version 5.10.3, and FreeBSD 12. Ensemble sharing is not yet implemented.

KNOWN IMPLEMENTATION STATUS

TCB data	Status
old_MMS_S	Not shared
old_MMS_R	Not shared
old_sendMSS	Cached and shared in Apple, Linux (MSS)
old_PMTU	Cached and shared in Apple, FreeBSD, Windows (PMTU)
old_RTT	Cached and shared in Apple, FreeBSD, Linux, Windows
old_RTTVAR	Cached and shared in Apple, FreeBSD, Windows
old_TFOinfo	Cached and shared in Apple, Linux, Windows
old_sendcwnd	Not shared
old_ssthresh	Cached and shared in Apple, FreeBSD*, Linux*
TFO failure	Cached and shared in Apple

In the table above, "Apple" refers to all Apple OSes, i.e., desktop/laptop macOS, phone iOS, pad iPadOS, video player tvOS, and watch watchOS, which all share the same Internet protocol stack.

*Note: In FreeBSD, new ssthresh is the mean of curr_ssthresh and previous value if a previous value exists; in Linux, the calculation depends on state and is $\max(\text{curr_cwnd}/2, \text{old_ssthresh})$ in most cases.

11. Changes Compared to RFC 2140

This document updates the description of TCB sharing in RFC 2140 and its associated impact on existing and new connection state, providing a complete replacement for that document [RFC2140]. It clarifies the previous description and terminology and extends the mechanism to its impact on new protocols and mechanisms, including multipath TCP, fast open, PLPMTUD, NAT, and the TCP Authentication Option.

The detailed impact on TCB state addresses TCB parameters in greater detail, addressing MSS in both the send and receive direction, MSS and sendMSS separately, adds path MTU and ssthresh, and addresses the impact on TCP option state.

New sections have been added to address compatibility issues and implementation observations. The relation of this work to T/TCP has been moved to 0 on history, partly to reflect the deprecation of that protocol.

Appendix C has been added to discuss the potential to use temporal sharing over long timescales to adapt TCP's initial window automatically, avoiding the need to periodically revise a single global constant value.

Finally, this document updates and significantly expands the referenced literature.

12. Security Considerations

These presented implementation methods do not have additional ramifications for direct (connection-aborting or information injecting) attacks on individual connections. Individual connections, whether using sharing or not, also may be susceptible to denial-of-service attacks that reduce performance or completely deny connections and transfers if not otherwise secured.

TCB sharing may create additional denial-of-service attacks that affect the performance of other connections by polluting the cached information. This can occur across whatever set of connections where the TCB is shared, between connections in a single host, or between hosts if TCB sharing is implemented within a subnet (see Implications section). Some shared TCB parameters are used only to create new TCBs, others are shared among the TCBs of ongoing connections. New connections can join the ongoing set, e.g., to optimize send window size among a set of connections to the same host. PMTU is defined as shared at the IP layer, and is already susceptible in this way.

Options in client SYNs can be easier to forge than complete, two-way connections. As a result, their values may not be safely incorporated in shared values until after the three-way handshake completes.

Attacks on parameters used only for initialization affect only the transient performance of a TCP connection. For short connections, the performance ramification can approach that of a denial-of-service attack. E.g., if an application changes its TCB to have a false and small window size, subsequent connections will experience performance degradation until their window grew appropriately.

TCB sharing reuses and mixes information from past and current connections. Although reusing information could create a potential for fingerprinting to identify hosts, the mixing reduces that potential. There has been no evidence of fingerprinting based on this technique and it is currently considered safe in that regard. Further, information about the performance of a TCP connection has not been considered as private.

13. IANA Considerations

There are no IANA implications or requests in this document.

This section should be removed upon final publication as an RFC.

15. Acknowledgments

The authors would like to thank for Praveen Balasubramanian for information regarding TCB sharing in Windows, Christoph Paasch for information regarding TCB sharing in Apple OSes, and Yuchung Cheng, Lars Eggert, Ilpo Jarvinen and Michael Scharf for comments on earlier versions of the draft, as well as members of the TCPM WG. Earlier revisions of this work received funding from a collaborative research project between the University of Oslo and Huawei Technologies Co., Ltd. and were partly supported by USC/ISI's Postel Center.

This document was prepared using 2-Word-v2.0.template.dot.

16. Change log

This section should be removed upon final publication as an RFC.

ietf-11:

- Addressed gen-art review and IESG feedback

ietf-10:

- Addressed IETF last call feedback

ietf-09:

- Correction of typographic errors

ietf-08:

- Address TSV AD comments, add Apple OS implementation status

ietf-07:

- Update per id-nits and normative language for consistency

ietf-06:

- Address WGLC comments

ietf-05:

- Correction of typographic errors, expansion of terminology

ietf-04:

- Fix internal cross-reference errors that appeared in ietf-02
- Updated tables to re-center; clarified text

ietf-03:

- Correction of typographic errors, minor rewording in appendices

ietf-02:

- Minor reorganization and correction of typographic errors
- Added text to address fingerprinting in Security section
- Now retains Appendix B and body option tables upon publication

ietf-01:

- Added Appendix C to address long-timescale temporal adaptation

ietf-00:

- Re-issued as draft-ietf-tcpm-2140bis due to WG adoption.
- Cleaned orphan references to T/TCP, removed incomplete refs
- Moved references to informative section and updated Sec 2
- Updated to clarify no impact to interoperability
- Updated appendix B to avoid 2119 language

06:

- Changed to update 2140, cite it normatively, and summarize the updates in a separate section

05:

- Fixed some TBDs

04:

- Removed BCP-style recommendations and fixed some TBDs

03:

- Updated Touch's affiliation and address information

02:

- Stated that our OS implementation overview table only covers temporal sharing.
- Correctly reflected sharing of old_RTT in Linux in the implementation overview table.
- Marked entries that are considered safe to share with an asterisk (suggestion was to split the table)
- Discussed correct host identification: NATs may make IP addresses the wrong input, could e.g., use HTTP cookie.
- Included MMS_S and MMS_R from RFC1122; fixed the use of MSS and MTU
- Added information about option sharing, listed options in Appendix B

Appendix A: TCB Sharing History

T/TCP proposed using caches to maintain TCB information across instances (temporal sharing), e.g., smoothed RTT, RTT variation, congestion avoidance threshold, and MSS [RFC1644]. These values were in addition to connection counts used by T/TCP to accelerate data delivery prior to the full three-way handshake during an OPEN. The goal was to aggregate TCB components where they reflect one association - that of the host-pair, rather than artificially separating those components by connection.

At least one T/TCP implementation saved the MSS and aggregated the RTT parameters across multiple connections but omitted caching the congestion window information [Br94], as originally specified in [RFC1379]. Some T/TCP implementations immediately updated MSS when the TCP MSS header option was received [Br94], although this was not addressed specifically in the concepts or functional specification [RFC1379][RFC1644]. In later T/TCP implementations, RTT values were updated only after a CLOSE, which does not benefit concurrent sessions.

Temporal sharing of cached TCB data was originally implemented in the SunOS 4.1.3 T/TCP extensions [Br94] and the FreeBSD port of same [FreeBSD]. As mentioned before, only the MSS and RTT parameters were cached, as originally specified in [RFC1379]. Later discussion of T/TCP suggested including congestion control parameters in this cache; for example, [RFC1644] (Section 3.1) hints at initializing the congestion window to the old window size.

Appendix B: TCP Option Sharing and Caching

In addition to the options that can be cached and shared, this memo also lists known TCP options [IANA] for which state is unsafe to be kept. This list is not intended to be authoritative or exhaustive.

Obsolete (unsafe to keep state):

ECHO

ECHO REPLY

PO Conn permitted

PO service profile

CC

CC.NEW

CC.ECHO

Alt CS req

Alt CS data

No state to keep:

EOL

NOP

WS

SACK

TS

MD5

TCP-AO

EXP1

EXP2

Unsafe to keep state:

Skeeter (DH exchange, known to be vulnerable)

Bubba (DH exchange, known to be vulnerable)

Trailer CS

SCPS capabilities

S-NACK

Records boundaries

Corruption experienced

SNAP

TCP Compression

Quickstart response

UTO

MPTCP negotiation success (see below for negotiation failure)

TFO negotiation success (see below for negotiation failure)

Safe but optional to keep state:

MPTCP negotiation failure (to avoid negotiation retries)

MSS

TFO negotiation failure (to avoid negotiation retries)

Safe and necessary to keep state:

TFO cookie (if TFO succeeded in the past)

Appendix C: Automating the Initial Window in TCP over Long Timescales

C.1. Introduction

Temporal sharing, as described earlier in this document, builds on the assumption that multiple consecutive connections between the same host pair are somewhat likely to be exposed to similar environment characteristics. The stored information can become less accurate over time and suitable precautions should take this ageing into consideration (this is discussed further in section 8.1). However, there are also cases where it can make sense to track these values over longer periods, observing properties of TCP connections to gradually influence evolving trends in TCP parameters. This appendix describes an example of such a case.

TCP's congestion control algorithm uses an initial window value (IW), both as a starting point for new connections and as an upper limit for restarting after an idle period [RFC5681][RFC7661]. This value has evolved over time, originally one maximum segment size (MSS), and increased to the lesser of four MSS or 4,380 bytes [RFC3390][RFC5681]. For a typical Internet connection with a maximum transmission unit (MTU) of 1500 bytes, this permits three segments of 1,460 bytes each.

The IW value was originally implied in the original TCP congestion control description and documented as a standard in 1997 [RFC2001][Ja88]. The value was updated in 1998 experimentally and moved to the standards track in 2002 [RFC2414][RFC3390]. In 2013, it was experimentally increased to 10 [RFC6928].

This appendix discusses how TCP can objectively measure when an IW is too large, and that such feedback should be used over long timescales to adjust the IW automatically. The result should be safer to deploy and might avoid the need to repeatedly revisit IW over time.

Note that this mechanism attempts to make the IW more adaptive over time. It can increase the IW beyond that which is currently recommended for widescale deployment, and so its use should be carefully monitored.

C.2. Design Considerations

TCP's IW value has existed statically for over two decades, so any solution to adjusting the IW dynamically should have similarly stable, non-invasive effects on the performance and complexity of TCP. In order to be fair, the IW should be similar for most machines

on the public Internet. Finally, a desirable goal is to develop a self-correcting algorithm, so that IW values that cause network problems can be avoided. To that end, we propose the following design goals:

- o Impart little to no impact to TCP in the absence of loss, i.e., it should not increase the complexity of default packet processing in the normal case.
- o Adapt to network feedback over long timescales, avoiding values that persistently cause network problems.
- o Decrease the IW in the presence of sustained loss of IW segments, as determined over a number of different connections.
- o Increase the IW in the absence of sustained loss of IW segments, as determined over a number of different connections.
- o Operate conservatively, i.e., tend towards leaving the IW the same in the absence of sufficient information, and give greater consideration to IW segment loss than IW segment success.

We expect that, without other context, a good IW algorithm will converge to a single value, but this is not required. An endpoint with additional context or information, or deployed in a constrained environment, can always use a different value. In particular, information from previous connections, or sets of connections with a similar path, can already be used as context for such decisions (as noted in the core of this document).

However, if a given IW value persistently causes packet loss during the initial burst of packets, it is clearly inappropriate and could be inducing unnecessary loss in other competing connections. This might happen for sites behind very slow boxes with small buffers, which may or may not be the first hop.

C.3. Proposed IW Algorithm

Below is a simple description of the proposed IW algorithm. It relies on the following parameters:

- o MinIW = 3 MSS or 4,380 bytes (as per [RFC3390])
- o MaxIW = 10 MSS (as per [RFC6928])
- o MulDecr = 0.5

- o AddIncr = 2 MSS
- o Threshold = 0.05

We assume that the minimum IW (MinIW) should be as currently specified as standard [RFC3390]. The maximum IW can be set to a fixed value (we suggest using the experimental and now somewhat de-facto standard in [RFC6928]) or set based on a schedule if trusted time references are available [Al10]; here we prefer a fixed value. We also propose to use an AIMD algorithm, with increase and decreases as noted.

Although these parameters are somewhat arbitrary, their initial values are not important except that the algorithm is AIMD and the MaxIW should not exceed that recommended for other systems on the Internet (here we selected the current de-facto standard rather than the actual standard). Current proposals, including default current operation, are degenerate cases of the algorithm below for given parameters - notably MulDec = 1.0 and AddIncr = 0 MSS, thus disabling the automatic part of the algorithm.

The proposed algorithm is as follows:

1. On boot:

```
IW = MaxIW; # assume this is in bytes, and indicates an integer
multiple of 2 MSS (an even number to support ACK compression)
```

2. Upon starting a new connection:

```
CWND = IW;
conncount++;
IWnotchecked = 1; # true
```

3. During a connection's SYN-ACK processing, if SYN-ACK includes ECN (as similarly addressed in Sec 5 of ECN++ for TCP [Ba20]), treat as if the IW is too large:

```
if (IWnotchecked && (synackecn == 1)) {
    losscount++;
    IWnotchecked = 0; # never check again
}
```

4. During a connection, if retransmission occurs, check the seqno of the outgoing packet (in bytes) to see if the resent segment fixes an IW loss:

```
if (Retransmitting && IWnotchecked && ((seqno - ISN) < IW)) {  
    losscount++;  
    IWnotchecked = 0; # never do this entire "if" again  
} else {  
    IWnotchecked = 0; # you're beyond the IW so stop checking  
}
```

5. Once every 1000 connections, as a separate process (i.e., not as part of processing a given connection):

```
if (conncount > 1000) {  
    if (losscount/conncount > threshold) {  
        # the number of connections with errors is too high  
        IW = IW * MulDecr;  
    } else {  
        IW = IW + AddIncr;  
    }  
}
```

As presented, this algorithm can yield a false positive when the sequence number wraps around, e.g., the code might increment losscount in step 4 when no loss occurred or fail to increment losscount when a loss did occur. This can be avoided using either PAWS [RFC7323] context or internal extended sequence number representations (as in TCP-AO [RFC5925]). Alternately, false positives can be tolerated because they are expected to be infrequent and thus will not significantly impact the algorithm.

A number of additional constraints need to be imposed if this mechanism is implemented to ensure that it defaults to values that comply with current Internet standards, is conservative in how it extends those values, and returns to those values in the absence of positive feedback (i.e., success). To that end, we recommend the following list of example constraints:

>> The automatic IW algorithm MUST initialize MaxIW a value no larger than the currently recommended Internet default, in the absence of other context information.

Thus, if there are too few connections to make a decision or if there is otherwise insufficient information to increase the IW, then the MaxIW defaults to the current recommended value.

>> An implementation MAY allow the MaxIW to grow beyond the currently recommended Internet default, but not more than 2 segments per calendar year.

Thus, if an endpoint has a persistent history of successfully transmitting IW segments without loss, then it is allowed to probe the Internet to determine if larger IW values have similar success. This probing is limited and requires a trusted time source, otherwise the MaxIW remains constant.

>> An implementation MUST adjust the IW based on loss statistics at least once every 1000 connections.

An endpoint needs to be sufficiently reactive to IW loss.

>> An implementation MUST decrease the IW by at least one MSS when indicated during an evaluation interval.

An endpoint that detects loss needs to decrease its IW by at least one MSS, otherwise it is not participating in an automatic reactive algorithm.

>> An implementation MUST increase by no more than 2 MSS per evaluation interval.

An endpoint that does not experience IW loss needs to probe the network incrementally.

>> An implementation SHOULD use an IW that is an integer multiple of 2 MSS.

The IW should remain a multiple of 2 MSS segments, to enable efficient ACK compression without incurring unnecessary timeouts.

>> An implementation MUST decrease the IW if more than 95% of connections have IW losses.

Again, this is to ensure an implementation is sufficiently reactive.

>> An implementation MAY group IW values and statistics within subsets of connections. Such grouping MAY use any information about connections to form groups except loss statistics.

There are some TCP connections which might not be counted at all, such as those to/from loopback addresses, or those within the same subnet as that of a local interface (for which congestion control is sometimes disabled anyway). This may also include connections that

terminate before the IW is full, i.e., as a separate check at the time of the connection closing.

The period over which the IW is updated is intended to be a long timescale, e.g., a month or so, or 1,000 connections, whichever is longer. An implementation might check the IW once a month, and simply not update the IW or clear the connection counts in months where the number of connections is too small.

C.4. Discussion

There are numerous parameters to the above algorithm that are compliant with the given requirements; this is intended to allow variation in configuration and implementation while ensuring that all such algorithms are reactive and safe.

This algorithm continues to assume segments because that is the basis of most TCP implementations. It might be useful to consider revising the specifications to allow byte-based congestion given sufficient experience.

The algorithm checks for IW losses only during the first IW after a connection start; it does not check for IW losses elsewhere the IW is used, e.g., during slow-start restarts.

>> An implementation MAY detect IW losses during slow-start restarts in addition to losses during the first IW of a connection. In this case, the implementation MUST count each restart as a "connection" for the purposes of connection counts and periodic rechecking of the IW value.

False positives can occur during some kinds of segment reordering, e.g., that might trigger spurious retransmissions even without a true segment loss. These are not expected to be sufficiently common to dominate the algorithm and its conclusions.

This mechanism does require additional per-connection state, which is currently common in some implementations, and is useful for other reasons (e.g., the ISN is used in TCP-AO [RFC5925]). The mechanism also benefits from persistent state kept across reboots, as would be other state sharing mechanisms (e.g., TCP Control Block Sharing per the main body of this document).

The receive window (rwnd) is not involved in this calculation. The size of rwnd is determined by receiver resources and provides space to accommodate segment reordering. It is not involved with

congestion control, which is the focus of this document and its management of the IW.

C.5. Observations

The IW may not converge to a single, global value. It also may not converge at all, but rather may oscillate by a few MSS as it repeatedly probes the Internet for larger IWs and fails. Both properties are consistent with TCP behavior during each individual connection.

This mechanism assumes that losses during the IW are due to IW size. Persistent errors that drop packets for other reasons - e.g., OS bugs, can cause false positives. Again, this is consistent with TCP's basic assumption that loss is caused by congestion and requires backoff. This algorithm treats the IW of new connections as a long-timescale backoff system.
