FlowQueue-Codel
draft-hoeiland-joergensen-aqm-fq-codel-01

Abstract

This memo presents the FQ-CoDel hybrid packet scheduler/AQM algorithm, a critical tool for fighting bufferbloat and reducing latency across the Internet.

FQ-CoDel mixes packets from multiple flows and reduces the impact of head of line blocking from bursty traffic. It provides isolation for low-rate traffic such as DNS, web, and videoconferencing traffic. It improves utilisation across the networking fabric, especially for bidirectional traffic, by keeping queue lengths short; and it can be implemented in a memory- and CPU-efficient fashion across a wide range of hardware.

Status of This Memo

This Internet-Draft is submitted in full conformance with the provisions of BCP 78 and BCP 79.

Internet-Drafts are working documents of the Internet Engineering Task Force (IETF). Note that other groups may also distribute working documents as Internet-Drafts. The list of current Internet-Drafts is at <http://datatracker.ietf.org/drafts/current/>.

Internet-Drafts are draft documents valid for a maximum of six months and may be updated, replaced, or obsoleted by other documents at any time. It is inappropriate to use Internet-Drafts as reference material or to cite them other than as "work in progress."

This Internet-Draft will expire on May 14, 2015.

1. Introduction

The FQ-CoDel algorithm is a combined packet scheduler and AQM developed as part of the bufferbloat-fighting community effort. It is based on a modified Deficit Round Robin (DRR) queue scheduler, with the CoDel AQM algorithm operating on each sub-queue. This document describes the combined algorithm; reference implementations are available for ns2 and ns3 and it is included in the mainline Linux kernel as the FQ-CoDel queueing discipline.

The rest of this document is structured as follows: This section gives some concepts and terminology used in the rest of the document, and gives a short informal summary of the FQ-CoDel algorithm. Section 2 gives an overview of the CoDel algorithm. Section 3 covers the DRR portion. Section 4 defines the parameters and data structures employed by FQ-CoDel. Section 5 describes the working of the algorithm in detail. Section 6 describes implementation considerations, and section 7 lists some of the limitations of using flow queueing. Finally section 11 concludes.

1.1. Terminology and concepts

Flow: A flow is typically identified by a 5-tuple of source IP, destination IP, source port, destination port, and protocol. It can also be identified by a superset or subset of those parameters, or by mac address, or other means.

Queue: A queue of packets represented internally in FQ-CoDel. In most instances each flow gets its own queue; however because of the possibility of hash collisions, this is not always the case. In an attempt to avoid confusion, the word 'queue' is used to refer to the internal data structure, and 'flow' to refer to the actual stream of packets being delivered to the FQ-CoDel algorithm.

Scheduler: A mechanism to select which queue a packet is dequeued from.

CoDel AQM: The Active Queue Management algorithm employed by FQ-CoDel.

DRR: Deficit round-robin scheduling.

Quantum: The maximum amount of bytes to be dequeued from a queue at once.

1.2. Informal summary of FQ-CoDel

FQ-CoDel is a hybrid of DRR [DRR] and CODEL [CODEL2012], with an optimisation for sparse flows similar to SQF [SQF2012] and DRR++ [DRRPP]. We call this "Flow Queueing" rather than "Fair Queueing" as flows that build a queue are treated differently than flows that do not.

FQ-CoDel stochastically classifies incoming packets into different sub-queues by hashing the 5-tuple of IP protocol number and source and destination IP and port numbers, perturbed with a random number selected at initiation time (although other flow classification schemes can optionally be configured instead). Each queue is managed by the CoDel queueing discipline. Packet ordering within a queue is preserved, since queues have FIFO ordering.

The FQ-CoDel algorithm consists of two logical parts: the scheduler which selects which queue to dequeue a packet from, and the CoDel AQM which works on each of the queues. The subtleties of FQ-CoDel are mostly in the scheduling part, whereas the interaction between the scheduler and the CoDel algorithm are fairly straight forward:

At initialisation, each queue is set up to have a separate set of CoDel state variables. By default, 1024 queues are created. The current implementation supports anywhere from one to 64K separate queues, and each queue maintains the state variables throughout its lifetime, and so acts the same as the non-FQ CoDel variant would. This means that with only one queue, FQ-CoDel behaves essentially the same as CoDel by itself.

On dequeue, FQ-CoDel selects a queue from which to dequeue by a two-tier round-robin scheme, in which each queue is allowed to dequeue up to a configurable quantum of bytes for each iteration. Deviations from this quantum is maintained as a deficit for the queue, which serves to make the fairness scheme byte-based rather than a packet-based. The two-tier round-robin mechanism distinguishes between "new" queues (which don't build up a standing queue) and "old"

queues, that have queued enough data to be around for more than one iteration of the round-robin scheduler.

This new/old queue distinction has a particular consequence for queues that don't build up more than a quantum of bytes before being visited by the scheduler: Such queues are removed from the list, and then re-added as a new queue each time a packet arrives for it, and so will get priority over queues that do not empty out each round (except for a minor modification to protect against starvation, detailed below). Exactly how much data a flow has to send to keep its queue in this state is somewhat difficult to reason about, because it depends on both the egress link speed and the number of concurrent flows. However, in practice many things that are beneficial to have prioritised for typical internet use (ACKs, DNS lookups, interactive SSH, HTTP requests, ARP, ICMP, VoIP) *tend* to fall in this category, which is why FQ-CoDel performs so well for many practical applications. However, the implicitness of the prioritisation means that for applications that require guaranteed priority (for instance multiplexing the network control plane over the network itself), explicit classification is still needed.

This scheduling scheme has some subtlety to it, which is explained in detail in the remainder of this document.

2. CoDel

CoDel is described in the the ACM Queue paper, CODEL [CODEL2012], and Van Jacobson's IETF84 presentation CODELDRAFT [CODELDRAFT]. The basic idea is to control queue length, maintaining sufficient queueing to keep the outgoing link busy, but avoiding building up the queue beyond that point. This is done by preferentially dropping packets that remain in the queue for "too long".

When each new packet arrives, its arrival time is stored with it. Later, when it is that packet's turn to be dequeued, CoDel computes its sojourn time (the current time minus the arrival time). If the sojourn time for packets being dequeued exceeds the *_target_* time for a time period of at least the (current value of) *_interval_*, one or more packets will be dropped (or marked, if ECN is enabled) in order to signal the source endpoint to reduce its send rate. If the sojourn still remains above the target time, the value of interval be lowered, and additional packet drops will occur on a schedule computed from an inverse-square-root control law until either (1) the queue becomes empty or (2) a packet is encountered with a sojourn time that is less than the target time. Upon exiting the dropping mode, CoDel caches the last calculated interval (applying varying amounts of hysteresis to it), to be used as the starting point on subsequent re-entries into dropping mode.

The `_target_` time is normally set to about five milliseconds, and the initial `_interval_` is normally set to about 100 milliseconds. This approach has proven to be quite effective in a wide variety of situations.

CoDel drops packets at the head of a queue, rather than at the tail.

3. Flow Queueing

FQ-CoDel's DRR scheduler is byte-based, employing a deficit round-robin mechanism between queues. This works by keeping track of the current byte `_deficit_` of each queue. This deficit is initialised to the configurable quantum; each time a queue gets a dequeue opportunity, it gets to dequeue packets, decreasing the deficit by the packet size for each packet, until the deficit runs into the negative, at which point it is increased by one quantum, and the dequeue opportunity ends.

This means that if one queue contains packets of size $\text{quantum}/3$, and another contains quantum-sized packets, the first queue will dequeue three packets each time it gets a turn, whereas the second only dequeues one. This means that flows that send small packets are not penalised by the difference in packet sizes; rather, the DRR scheme approximates a (single-)byte-based fairness queueing. The size of the quantum determines the scheduling granularity, with the tradeoff from too small a quantum being scheduling overhead. For small bandwidths, lowering the quantum from the default MTU size can be advantageous.

Unlike DRR there are two sets of flows - a "new" list for flows that have not built a queue recently, and an "old" list for flow-building queues.

4. FQ-CoDel Parameters and Data Structures

This section goes into the parameters and data structures in FQ-CoDel.

4.1. Parameters

4.1.1. Interval

The `_interval_` parameter has the same semantics as CoDel and is used to ensure that the measured minimum delay does not become too stale. The minimum delay MUST be experienced in the last epoch of length interval. It SHOULD be set on the order of the worst-case RTT through the bottleneck to give end-points sufficient time to react.

The default interval value is 100 ms.

4.1.2. Target

The `_target_` parameter has the same semantics as CoDel. It is the acceptable minimum standing/persistent queue delay for each FQ-CoDel Queue. This minimum delay is identified by tracking the local minimum queue delay that packets experience.

The default target value is 5 ms, but this value SHOULD be tuned to be at least the transmission time of a single MTU-sized packet at the prevalent egress link speed (which for e.g. 1Mbps and MTU 1500 is ~15ms). It should otherwise be set to on the order of 5-10% of the configured interval.

4.1.3. Packet limit

Routers do not have infinite memory, so some packet limit MUST be enforced.

The `_limit_` parameter is the hard limit on the real queue size, measured in number of packets. This limit is a global limit on the number of packets in all queues; each individual queue does not have an upper limit. When the limit is reached and a new packet arrives for enqueue, a packet is dropped from the head of the largest queue (measured in bytes) to make room for the new packet.

The default packet limit is 10240 packets, which is suitable for up to 10GigE speeds. In practice, the hard limit is rarely, if ever, hit, as drops are performed by the CoDel algorithm long before the limit is hit. For platforms that are severely memory constrained, a lower limit can be used.

4.1.4. Quantum

The `_quantum_` parameter is the number of bytes each queue gets to dequeue on each round of the scheduling algorithm. The default is set to 1514 bytes which corresponds to the Ethernet MTU plus the hardware header length of 14 bytes.

In TSO-enabled systems, where a "packet" consists of an offloaded packet train, it can presently be as large as 64K bytes. In GRO-enabled systems, up to 17 times the TCP max segment size (or 25K bytes).

4.1.5. Flows

The `_flows_` parameter sets the number of sub-queues into which the incoming packets are classified. Due to the stochastic nature of hashing, multiple flows may end up being hashed into the same slot.

This parameter can be set only at load time since memory has to be allocated for the hash table in the current implementation.

The default value is 1024.

4.1.6. ECN

ECN is `_enabled_` by default. Rather than do anything special with misbehaved ECN flows, FQ-CoDel relies on the packet scheduling system to minimise their impact, thus unresponsive packets in a flow being marked with ECN can grow to the overall packet limit, but will not otherwise affect the performance of the system.

It can be disabled by specifying the `_noecn_` parameter.

4.2. Data structures

4.2.1. Internal sub-queues

The main data structure of FQ-CoDel is the array of sub-queues, which is instantiated to the number of queues specified by the `_flows_` parameter at instantiation time. Each sub-queue consists simply of an ordered list of packets with FIFO semantics, two state variables tracking the queue deficit and total number of bytes enqueued, and the set of CoDel state variables. Other state variables to track queue statistics can also be included: for instance, the Linux implementation keeps a count of dropped packets.

Queue space is shared: there's a global limit on the number of packets the queues can hold, but not one per queue.

4.2.2. New and old queues lists

FQ-CoDel maintains two lists of active queues, called "new" and "old" queues. Each list is an ordered list containing references to the array of sub-queues. When a packet is added to a queue that is not currently active, that queue becomes active by being added to the list of new queues. Later on, it is moved to the list of old queues, from which it is removed when it is no longer active. This behaviour is the source of some subtlety in the packet scheduling at dequeue time, explained below.

5. The FQ-CoDel scheduler and AQM interactions

This section describes the operation of the FQ-CoDel scheduler and AQM. It is split into two parts explaining the enqueue and dequeue operations.

5.1. Enqueue

The packet enqueue mechanism consists of three stages: classification into a sub-queue, timestamping and bookkeeping, and optionally dropping a packet when the total number of enqueued packets goes over the maximum.

When a packet is enqueued, it is first classified into the appropriate sub-queue. By default, this is done by hashing on the 5-tuple of IP protocol, and source and destination IP and port numbers, permuted by a random value selected at initialisation time, and taking the hash value modulo the number of sub-queues. However, an implementation MAY also specify a configurable classification scheme along a wide variety of other possible parameters such as mac address, diffserv, firewall and flow specific markings, etc. (the Linux implementation does so in the form of the 'tc filter' command).

If a custom filter fails, classification failure results in the packet being dropped and no further action taken. By design the standard filter cannot fail.

Additionally, the default hashing algorithm presently deployed does decapsulation of some common packet types (6in4, IPIP, GRE 0), mixes IPv6 IP addresses thoroughly, and uses Jenkins hash on the result.

Once the packet has been successfully classified into a sub-queue, it is handed over to the CoDel algorithm for timestamping. It is then added to the tail of the selected queue, and the queue's byte count is updated by the packet size. Then, if the queue is not currently active (i.e. if it is not in either the list of new or the list of old queues), it is added to the end of the list of new queues, and its deficit is initiated to the configured quantum. Otherwise it is added to the old queue list.

Finally, the total number of enqueued packets is compared with the configured limit, and if it is above this value (which can happen since a packet was just enqueued), a packet is dropped from the head of the queue with the largest current byte count. Note that this in most cases means that the packet that gets dropped is different from the one that was just enqueued, and may even be from a different queue.

5.2. Dequeue

Most of FQ-CoDel's work is done at packet dequeue time. It consists of three parts: selecting a queue from which to dequeue a packet, actually dequeuing it (employing the CoDel algorithm in the process), and some final bookkeeping.

For the first part, the scheduler first looks at the list of new queues; for each queue in that list, if that queue has a negative deficit (i.e. it has already dequeued at least a quantum of bytes), its deficit is increased by one quantum, and the queue is put onto the end of the list of old queues, and the routine selects the next queue and starts again.

Otherwise, that queue is selected for dequeue. If the list of new queues is empty, the scheduler proceeds down the list of old queues in the same fashion (checking the deficit, and either selecting the queue for dequeuing, or increasing the deficit and putting the queue back at the end of the list).

After having selected a queue from which to dequeue a packet, the CoDel algorithm is invoked on that queue. This applies the CoDel control law, and may discard one or more packets from the head of that queue, before returning the packet that should be dequeued (or nothing if the queue is or becomes empty while being handled by the CoDel algorithm).

Finally, if the CoDel algorithm did not return a packet, the queue is empty, and the scheduler does one of two things: if the queue selected for dequeue came from the list of new queues, it is moved to the end of the list of old queues. If instead it came from the list of old queues, that queue is removed from the list, to be added back (as a new queue) the next time a packet arrives that hashes to that queue. Then (since no packet was available for dequeue), the whole dequeue process is restarted from the beginning.

If, instead, the scheduler `_did_` get a packet back from the CoDel algorithm, it updates the byte deficit for the selected queue before returning the packet as the result of the dequeue operation.

The step that moves an empty queue from the list of new queues to the list of old queues before it is removed is crucial to prevent starvation. Otherwise the queue could reappear (the next time a packet arrives for it) before the list of old queues is visited; this can go on indefinitely even with a small number of active flows, if the flow providing packets to the queue in question transmits at just the right rate. This is prevented by first moving the queue to the

list of old queues, forcing a pass through that, and thus preventing starvation.

The resulting migration of queues between the different states is summarised in the following state diagram:

6. Implementation considerations

6.1. Probability of hash collisions

Since the Linux FQ-CoDel implementation by default uses 1024 hash buckets, the probability that (say) 100 VoIP sessions will all hash to the same bucket is something like ten to the power of minus 300. Thus, the probability that at least one of the VoIP sessions will hash to some other queue is very high indeed.

Conversely, the probability that each of the 100 VoIP sessions will get its own queue is given by $(1023! / (924! * 1024^{99}))$ or about 0.007; so not all that probable. The probability rises sharply, however, if we are willing to accept a few collisions. For example, there is about an 86% probability that no more than two of the 100 VoIP sessions will be involved in any given collision, and about a 99% probability that no more than three of the VoIP sessions will be involved in any given collision. These last two results were computed using Monte Carlo simulations: Oddly enough, the mathematics for VoIP-session collision exactly matches that of hardware cache overflow.

6.2. Memory Overhead

FQ-CoDel can be implemented with a very low memory footprint (less than 64 bytes per queue on 64 bit systems). These are the data structures used in the Linux implementation:

```

struct codel_vars {
    u32          count;
    u32          lastcount;
    bool         dropping;
    u16          rec_inv_sqrt;
    codel_time_t first_above_time;
    codel_time_t drop_next;
    codel_time_t ldelay;
};

struct fq_codel_flow {
    struct sk_buff *head;
    struct sk_buff *tail;
    struct list_head flowchain;
    int deficit;
    u32 dropped; /* number of drops (or ECN marks) on this flow */
    struct codel_vars cvars;
};

```

The master table managing all queues looks like this:

```

struct fq_codel_sched_data {
    struct tcf_proto *filter_list; /* optional external classifier */
    struct fq_codel_flow *flows; /* Flows table [flows_cnt] */
    u32 *backlogs; /* backlog table [flows_cnt] */
    u32 flows_cnt; /* number of flows */
    u32 perturbation; /* hash perturbation */
    u32 quantum; /* psched_mtu(qdisc_dev(sch)); */
    struct codel_params cparams;
    struct codel_stats cstats;
    u32 drop_overlimit;
    u32 new_flow_count;

    struct list_head new_flows; /* list of new flows */
    struct list_head old_flows; /* list of old flows */
};

```

6.3. Per-Packet Timestamping

The CoDel portion of the algorithm requires per-packet timestamps be stored along with the packet. While this approach works well for software-based routers, it may be impossible to retrofit devices that do most of their processing in silicon and lack space or mechanism for timestamping.

Also, while perfect resolution is not needed, timestamping functions in the core OS need to be efficient as they are called at least once on each packet enqueue and dequeue.

6.4. Other forms of "Fair Queueing"

Much of the scheduling portion of FQ-CoDel is derived from DRR and is substantially similar to DRR++. SFQ-based versions have also been produced and tested in ns2. Other forms of Fair Queueing, such as WFQ or QFQ, have not been thoroughly explored.

6.5. Differences between CoDel and FQ-CoDel behaviour

CoDel can be applied to a single queue system as a straight AQM, where it converges towards an "ideal" drop rate (i.e. one that minimises delay while keeping a high link utilisation), and then optimises around that control point.

The scheduling of FQ-CoDel mixes packets of competing flows, which acts to pace bursty flows to better fill the pipe. Additionally, a new flow gets substantial "credit" over other flows until CoDel finds an ideal drop rate for it. However, for a new flow that exceeds the configured quantum, more time passes before all of its data is delivered (as packets from it, too, are mixed across the other existing queue-building flows). Thus, FQ-CoDel takes longer (as measured in time) to converge towards an ideal drop rate for a given new flow, but does so within fewer delivered `_packets_` from that flow.

Finally, the flow isolation FQ-CoDel provides means that the CoDel drop mechanism operates on the flows actually building queues, which results in packets being dropped more accurately from the largest flows than CoDel alone manages. Additionally, flow isolation radically improves the transient behaviour of the network when traffic or link characteristics change (e.g. when new flows start up or the link bandwidth changes); while CoDel itself can take a while to respond, `fq_codel` doesn't miss a beat.

7. Limitations of flow queueing

While FQ-CoDel has been shown in many scenarios to offer significant performance gains, there are some scenarios where the scheduling algorithm in particular is not a good fit. This section documents some of the known cases which either may require tweaking the default behaviour, or where alternatives to flow queueing should be considered.

7.1. Fairness between things other than flows

In some parts of the network, enforcing flow-level fairness may not be desirable, or some other level of fairness may be more important. An example of this can be an Internet Service Provider that may be

more interested in ensuring fairness between customers than between flows. Or a hosting or transit provider that wishes to ensure fairness between connecting Autonomous Systems or networks. Another issue can be that the number of simultaneous flows experienced at a particular link can be too high for flow-based fairness queueing to be effective.

Whatever the reason, in a scenario where fairness between flows is not desirable, reconfiguring FQ-CoDel to match on a different characteristic can be a way forward. The implementation in Linux can leverage the powerful packet matching mechanism of the `_tc_` subsystem to use any available packet field to partition packets into virtual queues, to for instance match on address or subnet source/destination pairs, application layer characteristics, etc.

Furthermore, as commonly deployed today, FQ-CoDel is used with three or more tiers of classification: priority, best effort and background, based on diffserv markings. Some products do more detailed classification, including deep packet inspection and destination-specific filters to achieve their desired result.

7.2. Flow bunching by opaque encapsulation

Where possible, FQ-CoDel will attempt to decapsulate packets before matching on the header fields for the flow hashing. However, for some encapsulation techniques, most notably encrypted VPNs, this is not possible. If several flows are bunched into one such encapsulated tunnel, they will be seen as one flow by the FQ-CoDel algorithm. This means that they will share a queue, and drop behaviour, and so flows inside the encapsulation will not benefit from the implicit prioritisation of FQ-CoDel, but will continue to benefit from the reduced overall queue length from the CoDel algorithm operating on the queue. In addition, when such an encapsulated bunch competes against other flows, it will count as one flow, and not assigned a share of the bandwidth based on how many flows are inside the encapsulation.

Depending on the application, this may or may not be desirable behaviour. In cases where it is not, changing FQ-CoDel's matching to not be flow-based (as detailed in the previous subsection above) can be a way to mitigate this.

7.3. Low-priority congestion control algorithms

Because of the flow isolation that FQ-CoDel provides, low-priority congestion control algorithms (or, in general, algorithms that try to voluntarily use up less than their fair share of bandwidth) can be re-prioritised. Because a flow experiences very little added latency

when the link is congested, such algorithms lack the signal to back off that added latency previously afforded them. As such, existing algorithms tend to revert to loss-based congestion control, and will consume the fair share of bandwidth afforded to them by the FQ-CoDel scheduler. However, low-priority congestion control mechanisms may be able to take steps to continue to be low priority, for instance by taking into account the vastly reduced level of delay afforded by an AQM, or by using a coupled approach to observing the behaviour of multiple flows.

8. Security Considerations

There are no specific security exposures associated with FQ-CoDel. Some exposures present in current FIFO systems are in fact reduced (e.g. simple minded packet floods).

9. IANA Considerations

This document has no actions for IANA.

10. Acknowledgements

Our deepest thanks to Eric Dumazet (author of FQ-CoDel), Kathie Nichols, Van Jacobson, and all the members of the `bufferbloat.net` effort.

11. Conclusions

FQ-CoDel is a very general, efficient, nearly parameterless active queue management approach combining flow queueing with CoDel. It is a critical tool in solving bufferbloat.

FQ-CoDel's default settings SHOULD be modified for other special-purpose networking applications, such as for exceptionally slow links, for use in data centres, or on links with inherent delay greater than 800ms (e.g. satellite links).

On-going projects are: improving FQ-CoDel with more SFQ-like behaviour for lower bandwidth systems, improving the control law, optimising sparse packet drop behaviour, etc..

In addition to the Linux kernel sources, ns2 and ns3 models are available. Refinements (such as NFQCODEL [1]) are being tested in the CeroWrt effort.

The Benefits of using Explicit Congestion Notification (ECN)
draft-ietf-aqm-ecn-benefits-08

Abstract

The goal of this document is to describe the potential benefits when applications use a transport that enables Explicit Congestion Notification (ECN). The document outlines the principal gains in terms of increased throughput, reduced delay and other benefits when ECN is used over a network path that includes equipment that supports Congestion Experienced (CE) marking. It also discusses challenges for successful deployment of ECN. It does not propose new algorithms to use ECN, nor does it describe the details of implementation of ECN in endpoint devices (Internet hosts), routers or other network devices.

Status of This Memo

This Internet-Draft is submitted in full conformance with the provisions of BCP 78 and BCP 79.

Internet-Drafts are working documents of the Internet Engineering Task Force (IETF). Note that other groups may also distribute working documents as Internet-Drafts. The list of current Internet-Drafts is at <http://datatracker.ietf.org/drafts/current/>.

Internet-Drafts are draft documents valid for a maximum of six months and may be updated, replaced, or obsoleted by other documents at any time. It is inappropriate to use Internet-Drafts as reference material or to cite them other than as "work in progress."

This Internet-Draft will expire on May 27, 2016.

1. Introduction

Internet Transports (such as TCP and SCTP) are implemented in endpoints (Internet hosts) and are designed to detect and react to network congestion. Congestion may be detected by loss of an IP packet or, if Explicit Congestion Notification (ECN) [RFC3168] is enabled, by the reception of a packet with a Congestion Experienced (CE) marking in the IP header. Both of these are treated by transports as indications of congestion. ECN may also be enabled by

other transports: UDP applications that provide congestion control may enable ECN when they are able to correctly process the ECN signals [ID.RFC5405.bis] (e.g., ECN with RTP [RFC6679]).

Active Queue Management (AQM) [RFC7567] is a class of techniques that can be used by network devices (a router, middlebox, or other device that forwards packets through the network) to manage the size of queues in network buffers.

A network device that does not support AQM typically uses a drop-tail policy to drop excess IP packets when its queue becomes full. The discard of packets is treated by transport protocols as a signal that indicates congestion on the end-to-end network path. End-to-end transports, such as TCP, can cause a low level of loss while seeking to share capacity with other flows. Although losses are not always due to congestion (loss may be due to link corruption, receiver-overflow, etc) end points have to conservatively presume that all loss is potentially due to congestion and reduce their rate. Observed loss therefore results in a congestion control reaction by the transport to reduce the maximum rate permitted by the sending endpoint.

ECN makes it possible for the network to signal the presence of incipient congestion without incurring packet loss, it lets the network deliver some packets to an application that would otherwise have been dropped if the application or transport did not support ECN. This packet loss reduction is the most obvious benefit of ECN, but it is often relatively modest. However, enabling ECN can also result in a number of beneficial side-effects, some of which may be much more significant than the immediate packet loss reduction from receiving CE-marking instead of dropping packets. Several benefits reduce latency (e.g., reduced Head-of-Line Blocking).

The use of ECN is indicated in the ECN field [RFC3168], carried in the packet header of all IPv4 and IPv6 packets. This field may be set to one of four values shown in Table 1. The not-ECT codepoint '00' indicates a packet that is not using ECN. The ECT(0) codepoint '01' and the ECT(1) codepoint '10' both indicate that the transport protocol using the IP layer supports the use of ECN. The CE codepoint '11' is set by an ECN-capable network device to indicate congestion to the transport endpoint.

ECN FIELD		Name
0	0	Not-ECT
0	1	ECT(1)
1	0	ECT(0)
1	1	CE

Table 1: The ECN Field in the IP Packet Header (based on [RFC3168]).

When an application uses a transport that enables use of ECN [RFC3168], the transport layer sets the ECT(0) or ECT(1) codepoint in the IP header of packets that it sends. This indicates to network devices that they may mark, rather than drop the ECN-capable IP packets. An ECN-capable network device can then signal incipient congestion (network queueing) at a point before a transport experiences congestion loss or high queuing delay. The marking is generally performed as the result of various AQM algorithms [RFC7567], where the exact combination of AQM/ECN algorithms does not need to be known by the transport endpoints.

The focus of the document is on usage of ECN by transport and application layer flows, not its implementation in endpoint hosts, or in routers and other network devices.

1.1. Terminology

The following terms are used:

AQM: Active Queue Management.

CE: Congestion Experienced, a codepoint value '11' marked in the ECN field of the IP packet header.

ECN-capable IP Packet : A packet where the ECN field is set to a non-zero ECN value (i.e., with a ECT(0), ECT(1), or the CE codepoint).

ECN-capable network device : An ECN-capable network device may forward, drop, or queue an ECN-capable packet and may choose to CE-mark this packet when there is incipient congestion.

ECN-capable transport/application : A transport that sends ECN-capable IP Packets, and monitors reception of the ECN field and generates appropriate feedback to control the rate of the sending endpoint.

to provide end-to-end congestion control.

ECN field: A 2-bit field specified for use explicit congestion signalling in the IPv4 and IPv6 packet headers.

Endpoint: An Internet host that terminates a transport protocol connection across an Internet path.

Incipient Congestion: The detection of congestion when it is starting, perhaps by a network device noting that the arrival rate exceeds the forwarding rate.

Network device: A router, middlebox, or other device that forwards IP packets through the network.

non-ECN-capable: A network device or endpoint that does not interpret the ECN field. Such a device is not permitted to change the ECN codepoint.

not-ECN-capable IP Packet: An IP packet with the ECN field set to a value of zero ('00'). A not-ECN-capable packet may be forwarded, dropped or queued by a network device.

2. Benefit of using ECN to avoid Congestion Loss

An ECN-capable network device is expected to CE-mark an ECN-capable IP packet when an AQM method detects incipient congestion, rather than to drop the packet [RFC7567]. An application can benefit from this marking in several ways:

2.1. Improved Throughput

ECN seeks to avoid the inefficiency of dropping data that has already made it across at least part of the network path.

ECN can improve the throughput of an application, although this increase in throughput is often not the most significant gain. When an application uses a light to moderately loaded network path, the number of packets that are dropped due to congestion is small. Using an example from Table 1 of [RFC3649], for a standard TCP sender with a Round Trip Time, RTT, of 0.1 seconds, a packet size of 1500 bytes and an average throughput of 1 Mbps, the average packet drop ratio would be 0.02 (i.e., 1 in 50 packets). This translates into an approximate 2% throughput gain if ECN is enabled. (Note that in heavy congestion, packet loss may be unavoidable with, or without, ECN.)

2.2. Reduced Head-of-Line Blocking

Many Internet transports provide in-order delivery of received data segments to the applications they support. For these applications, use of ECN can reduce the delay that can result when these applications experience packet loss.

Packet loss may occur for various reasons. One cause arises when an AQM scheme drops a packet as a signal of incipient congestion. Whatever the cause of loss, a missing packet needs to trigger a congestion control response. A reliable transport also triggers retransmission to recover the lost data. For a transport providing in-order delivery, this requires that the transport receiver stalls (or waits) for all data that was sent ahead of a lost segment to be correctly received before it can forward any later data to the application. A loss therefore creates a delay of at least one RTT after a loss event before data can be delivered to an application. We call this Head-of-Line (HOL) blocking. This is the usual requirement for TCP and SCTP. (PR-SCTP [RFC3758], UDP [RFC0768][ID.RFC5405.bis], and DCCP [RFC4340] provide a transport that does not provide re-ordering).

By enabling ECN, a transport continues to receive in-order data when there is incipient congestion, and can pass this data to the receiving application. Use of ECN avoids the additional reordering delay in a reliable transport. The sender still needs to make an appropriate congestion-response to reduce the maximum transmission rate for future traffic, which usually will require a reduction in the sending rate [ID.RFC5405.bis].)

2.3. Reduced Probability of RTO Expiry

Some patterns of packet loss can result in a Retransmission Time Out (RTO), which causes a sudden and significant change in the allowed rate at which a transport/application can forward packets. Because ECN provides an alternative to drop for network devices to signal incipient congestion, this can reduce the probability of loss and hence reduce the likelihood of RTO expiry.

Internet transports/applications generally use a RTO timer as a last resort to detect and recover loss [ID.RFC5405.bis] [RFC5681]). Specifically, a RTO timer detects loss of a packet that is not followed by other packets, such as at the end of a burst of data segments or when an application becomes idle (either because the application has no further data to send or the network prevents sending further data, e.g., flow or congestion control at the transport layer). This loss of the last segment (or last few segments) of a traffic burst is also known as a "tail loss".

Standard transport recovery methods, such as Fast Recovery ([RFC5681]), are often unable to recover from a tail loss. This is because the endpoint receiver is unaware that the lost segments were actually sent, and therefore generates no feedback [Fla13]. Retransmission of these segments therefore relies on expiry of a transport retransmission timer. This timer is also used to detect a lack of forwarding along a path. Expiry of the RTO therefore results in the consequent loss of state about the network path being used. This typically includes resetting path estimates such as the RTT, re-initialising the congestion window, and possibly updates to other transport state. This can reduce the performance of the transport until it again adapts to the path.

An ECN-capable network device cannot eliminate the possibility of tail loss, because a drop may occur due to a traffic burst exceeding the instantaneous available capacity of a network buffer or as a result of the AQM algorithm (overload protection mechanisms, etc [RFC7567]). However, an ECN-capable network device that observes incipient congestion may be expected to buffer the IP packets of an ECN-capable flow and set a CE-mark in one or more packet(s), rather than triggering packet drop. Setting a CE-mark signals incipient congestion without forcing the transport/application to enter retransmission timeout. This reduces application-level latency and can improve the throughput for applications that send intermittent bursts of data.

The benefit of avoiding retransmission loss is expected to be significant when ECN is used on TCP SYN/ACK packets [RFC5562] where the RTO interval may be large because TCP cannot base the timeout period on prior RTT measurements from the same connection.

2.4. Applications that do not Retransmit Lost Packets

A transport that enables ECN can receive timely congestion signals without the need to retransmit packets each time it receives a congestion signal.

Some latency-critical applications do not retransmit lost packets, yet may be able to adjust their sending rate following detection of incipient congestion. Examples of such applications include UDP-based services that carry Voice over IP (VoIP), interactive video, or real-time data. The performance of many such applications degrades rapidly with increasing packet loss and the transport/application may therefore employ mechanisms (e.g., packet forward error correction, data duplication, or media codec error concealment) to mitigate the immediate effect of congestion loss on the application. Some mechanisms consume additional network capacity, some require additional processing and some contribute additional path latency

when congestion is experienced. By decoupling congestion control from loss, ECN can allow transports that support these applications to reduce their rate before the application experiences loss from congestion. This can reduce the negative impact of triggering loss-hiding mechanisms with a direct positive impact on the quality experienced by the users of these applications.

2.5. Making Incipient Congestion Visible

A characteristic of using ECN is that it exposes the presence of congestion on a network path to the transport and network layers allowing information to be collected about the presence of incipient congestion.

Recording the presence of CE-marked packets can provide information about the current congestion level experienced on a network path. A network flow that only experiences CE-marking and no loss implies that the sending endpoint is experiencing only congestion. A network flow may also experience loss (e.g., due to queue overflow, AQM methods that protect other flows, link corruption or loss in middleboxes). When a mixture of CE-marking and packet loss is experienced, transports and measurements need to assume there is congestion [RFC7567]. An absence of CE-marks therefore does not indicate a path has not experienced congestion.

The reception of CE-marked packets can be used to monitor the level of congestion by a transport/application or a network operator. For example, ECN measurements are used by Congestion Exposure (ConEx) [RFC6789]. In contrast, metering packet loss is harder.

2.6. Opportunities for new Transport Mechanisms

ECN can enable design and deployment of new algorithms in network devices and Internet transports. Internet transports need to regard both loss and CE-marking as an indication of congestion. However, while the amount of feedback provided by drop ought naturally to be minimized, this is not the case for ECN. In contrast, an ECN-Capable network device could provide richer (more frequent and fine-grained) indication of its congestion state to the transport.

For any ECN-capable transport, the receiving endpoint needs to provide feedback to the transport sender to indicate that CE-marks have been received. [RFC3168] provides one method that signals once each round trip time that CE-marked packets have been received.

A receiving endpoint may provide more detailed feedback to the congestion controller at the sender (e.g., describing the set of received ECN codepoints, or indicating each received CE-marked

packet). Precise feedback about the number of CE-marks encountered is supported by the Real Time Protocol (RTP) when used over UDP [RFC6679] and has been proposed for SCTP [ST14] and TCP [ID.Acc.ECN].

More detailed feedback is expected to enable evolution of transport protocols allowing the congestion control mechanism to make a more appropriate decision on how to react to congestion. Designers of transport protocols need to consider not only how network devices CE-mark packets, but also how the control loop in the application/transport reacts to reception of these CE-marked packets.

Benefit has been noted when packets are CE-marked early using an instantaneous queue, and if the receiving endpoint provides feedback about the number of packet marks encountered, an improved sender behavior has been shown to be possible, e.g, Datacenter TCP (DCTCP) [AL10]. DCTCP is targeted at controlled environments such as a datacenter. This is work-in-progress and it is currently unknown whether or how such behaviour could be safely introduced into the Internet. Any update to an Internet transport protocol requires careful consideration of the robustness of the behaviour when working with endpoints or network devices that were not designed for the new congestion reaction.

3. Network Support for ECN

For an application to use ECN requires that the endpoints first enable ECN within the transport being used, but also for all network devices along the path to at least forward IP packets that set a non-zero ECN codepoint.

ECN can be deployed both in the general Internet and in controlled environments:

- o ECN can be incrementally deployed in the general Internet. The IETF has provided guidance on configuration and usage in [RFC7567].
- o ECN may be deployed within a controlled environment, for example within a data centre or within a well-managed private network. This use of ECN may be tuned to the specific use-case. An example is DCTCP [AL10] [ID.DCTCP].

Early experience of using ECN across the general Internet encountered a number of operational difficulties when the network path either failed to transfer ECN-capable packets or inappropriately changed the ECN codepoints [BA11]. A recent survey reported a growing support for network paths to pass ECN codepoints [TR15].

The remainder of this section identifies what is needed for network devices to effectively support ECN.

3.1. The ECN Field

The current IPv4 and IPv6 specifications assign usage of 2 bits in the IP header to carry the ECN codepoint. This 2-bit field was reserved in [RFC2474] and assigned in [RFC3168].

[RFC4774] discusses some of the issues in defining alternate semantics for the ECN field, and specifies requirements for a safe coexistence in an Internet that could include routers that do not understand the defined alternate semantics.

Some network devices were configured to use a routing hash that included the set of 8 bits forming the now deprecated Type of Service (ToS) field [RFC1349]. The present use of this field assigns 2 of these bits to carry the ECN field. This is incompatible with use in a routing hash, because it could lead to IP packets that carry a CE-mark being routed over a different path to those packets that carried an ECT mark. The resultant reordering would impact the performance of transport protocols (such as TCP or SCTP) and UDP-based applications that are sensitive to reordering. A network device that conforms to this older specification needs to be updated to the current specifications [RFC2474] to support ECN. Configuration of network devices must note that the ECN field may be updated by any ECN-capable network device along a path.

3.2. Forwarding ECN-Capable IP Packets

Not all network devices along a path need to be ECN-capable (i.e., perform CE-marking). However, all network devices need to be configured not to drop packets solely because the ECT(0) or ECT(1) codepoints are used.

Any network device that does not perform CE-marking of an ECN-capable packet can be expected to drop these packets under congestion. Applications that experience congestion at these network devices do not see any benefit from enabling ECN. However, they may see benefit if the congestion were to occur within a network device that did support ECN.

3.3. Enabling ECN in Network Devices

Network devices should use an AQM algorithm that CE-marks ECN-capable traffic when making decisions about the response to congestion [RFC7567]. An ECN method should set a CE-mark on ECN-capable packets in the presence of incipient congestion. A CE-marked packet will be

interpreted as an indication of incipient congestion by the transport endpoints.

There is opportunity to design an AQM method for an ECN-capable network device that differs from an AQM method designed to drop packets. [RFC7567] states that the network device should allow this behaviour to be configurable.

[RFC3168] describes a method in which a network device sets the CE-mark at the time that the network device would otherwise have dropped the packet. While it has often been assumed that network devices should CE-mark packets at the same level of congestion at which they would otherwise have dropped them, [RFC7567] recommends that network devices allow independent configuration of the settings for AQM dropping and ECN marking. Such separate configuration of the drop and mark policies is supported in some network devices.

3.4. Co-existence of ECN and non-ECN flows

Network devices need to be able to forward all IP flows and provide appropriate treatment for both ECN and non-ECN traffic.

The design considerations for an AQM scheme supporting ECN needs to consider the impact of queueing during incipient congestion. For example, a simple AQM scheme could choose to queue ECN-capable and non-ECN capable flows in the same queue with an ECN scheme that CE-mark packets during incipient congestion. The CE-marked packets that remain in the queue during congestion can continue to contribute to queueing delay. In contrast, non-ECN-capable packets would normally be dropped by an AQM scheme under incipient congestion. This difference in queueing is one motivation for consideration of more advanced AQM schemes, and may provide an incentive for enabling flow isolation using scheduling [RFC7567]. The IETF is defining methods to evaluate the suitability of AQM schemes for deployment in the general Internet [ID.AQM.eval].

3.5. Bleaching and Middlebox Requirements to deploy ECN

Network devices should not be configured to change the ECN codepoint in the packets that they forward, except to set the CE-codepoint to signal incipient congestion.

Cases have been noted where an endpoint sends a packet with a non-zero ECN mark, but the packet is received by the remote endpoint with a zero ECN codepoint [TR15]. This could be a result of a policy that erases or "bleaches" the ECN codepoint values at a network edge (resetting the codepoint to zero). Bleaching may occur for various

reasons (including normalising packets to hide which equipment supports ECN). This policy prevents use of ECN by applications.

When ECN-capable IP packets, marked as ECT(0) or ECT(1), are remarked to non-ECN-capable (i.e., the ECN field is set to zero codepoint), this could result in the packets being dropped by ECN-capable network devices further along the path. This eliminates the advantage of using of ECN.

A network device must not change a packet with a CE mark to a zero codepoint, if the network device decides not to forward the packet with the CE-mark, it has to instead drop the packet and not bleach the marking. This is because a CE-marked packet has already received ECN treatment in the network, and remarking it would then hide the congestion signal from the receiving endpoint. This eliminates the benefits of ECN. It can also slow down the response to congestion compared to using AQM, because the transport will only react if it later discovers congestion by some other mechanism.

Prior to RFC2474, a previous usage assigned the bits now forming the ECN field as a part of the now deprecated Type of Service (ToS) field [RFC1349]. A network device that conforms to this older specification was allowed to remark or erase the ECN codepoints, and such equipment needs to be updated to the current specifications to support ECN.

3.6. Tunneling ECN and the use of ECN by Lower Layer Networks

Some networks may use ECN internally or tunnel ECN (e.g., for traffic engineering or security). These methods need to ensure that the ECN-field of the tunnel packets is handled correctly at the ingress and egress of the tunnel. Guidance on the correct use of ECN is provided in [RFC6040].

Further guidance on the encapsulation and use of ECN by non-IP network devices is provided in [ID.ECN-Encap].

4. Using ECN across the Internet

A receiving endpoint needs to report the loss it experiences when it uses loss-based congestion control. So also, when ECN is enabled, a receiving endpoint must correctly report the presence of CE-marks by providing a mechanism to feed this congestion information back to the sending endpoint, [RFC3168], [ID.RFC5405.bis], enabling the sender to react to experienced congestion. This mechanism needs to be designed to operate robustly across a wide range of Internet path characteristics. This section describes partial deployment, how ECN-enabled endpoints can continue to work effectively over a path that

experiences misbehaving network devices or when an endpoint does not correctly provide feedback of ECN congestion information.

4.1. Partial Deployment

Use of ECN is negotiated between the endpoints prior to using the mechanism.

ECN has been designed to allow incremental partial deployment [RFC3168]. Any network device can choose to use either ECN or some other loss-based policy to manage its traffic. Similarly, transport/application negotiation allows senders and receiving endpoints to choose whether ECN will be used to manage congestion for a particular network flow.

4.2. Detecting whether a Path Really Supports ECN

Internet transport and applications need to be robust to the variety and sometimes varying path characteristics that are encountered in the general Internet. They need to monitor correct forwarding of ECN over the entire path and duration of a session.

To be robust, applications and transports need to be designed with the expectation of heterogeneous forwarding (e.g., where some IP packets are CE-marked by one network device, and some by another, possibly using a different AQM algorithm, or when a combination of CE-marking and loss-based congestion indications are used. ([ID.AQM.eval] describes methodologies for evaluating AQM schemes.)

A transport/application also needs to be robust to path changes. A change in the set of network devices along a path could impact the ability to effectively signal or use ECN across the path, e.g., when a path changes to use a middlebox that bleaches ECN codepoints (see Section 3.5).

A sending endpoint can check that any CE-marks applied to packets received over the path are indeed delivered to the remote receiving endpoint and that appropriate feedback is provided. (This could be done by a sender setting known a CE codepoint for specific packets in a network flow and then checking whether the remote endpoint correctly reports these marks [ID.Fallback], [TR15].) If a sender detects persistent misuse of ECN, it needs to fall back to using loss-based recovery and congestion control. Guidance on a suitable transport reaction is provided in [ID.Fallback].

4.3. Detecting ECN Receiver Feedback Cheating

Appropriate feedback requires that the endpoint receiver does not try to conceal reception of CE-marked packets in the ECN feedback information provided to the sending endpoint [RFC7567]. Designers of applications/transports are therefore encouraged to include mechanisms that can detect this misbehavior. If a sending endpoint detects that a receiver is not correctly providing this feedback, it needs to fall back to using loss-based recovery instead of ECN.

5. Summary: Enabling ECN in Network Devices and Hosts

This section summarises the benefits of deploying and using ECN within the Internet. It also provides a list of prerequisites to achieve ECN deployment.

Application developers should where possible use transports that enable ECN. Applications that directly use UDP need to provide support to implement the functions required for ECN [ID.RFC5405.bis]. Once enabled, an application that uses a transport that supports ECN will experience the benefits of ECN as network deployment starts to enable ECN. The application does not need to be rewritten to gain these benefits. Table 2 summarises the key benefits.

Section	Benefit
2.1	Improved throughput
2.2	Reduced Head-of-Line blocking
2.3	Reduced probability of RTO Expiry
2.4	Applications that do not retransmit lost packets
2.5	Making incipient congestion visible
2.6	Opportunities for new transport mechanisms

Table 2: Summary of Key Benefits

Network operators and people configuring network devices should enable ECN [RFC7567].

Prerequisites for network devices (including IP routers) to enable use of ECN include:

- o A network device that updates the ECN field in IP packets must use IETF-specified methods (see Section 3.1).

- o A network device may support alternate ECN semantics (see Section 3.1).
- o A network device must not choose a different network path solely because a packet carries has a CE-codepoint set in the ECN Field, CE-marked packets need to follow the same path as packets with an ECT(0) or ECT(1) codepoint (see Section 3.1). Network devices need to be configured not to drop packets solely because the ECT(0) or ECT(1) codepoints are used (see Section 3.2).
- o A network device must not change a packet with a CE mark to a not-ECN-capable codepoint ('00'), if the network device decides not to forward the packet with the CE-mark, it has to instead drop the packet and not bleach the marking (see Section 3.5).
- o An ECN-capable network device should correctly update the ECN codepoint of ECN-capable packets in the presence of incipient congestion (see Section 3.3).
- o Network devices need to be able to forward both ECN-capable and not-ECN-capable flows (see Section 3.4).

Prerequisites for network endpoints to enable use of ECN include:

- o An application should use an Internet transport that can set and receive ECN marks (see Section 4).
- o An ECN-capable transport/application must return feedback indicating congestion to the sending endpoint and perform an appropriate congestion response (see Section 4).
- o An ECN-capable transport/application should detect paths where there is there is persistent misuse of ECN and fall back to not sending ECT(0) or ECT(1) (see Section 4.2).
- o Designers of applications/transports are encouraged to include mechanisms that can detect and react appropriately to misbehaving receivers that fail to report CE-marked packets (see Section 4.3).

6. Acknowledgements

The authors were part-funded by the European Community under its Seventh Framework Programme through the Reducing Internet Transport Latency (RITE) project (ICT-317700). The views expressed are solely those of the authors.

The authors would like to thank the following people for their comments on prior versions of this document: Bob Briscoe, David

Collier-Brown, Colin Perkins, Richard Scheffenegger, Dave Taht, Wes Eddy, Fred Baker, Mikael Abrahamsson, Mirja Kuehlewind, John Leslie, and other members of the TSVWG and AQM working groups.

7. IANA Considerations

XX RFC Ed - PLEASE REMOVE THIS SECTION XXX

This memo includes no request to IANA.

8. Security Considerations

This document introduces no new security considerations. Each RFC listed in this document discusses the security considerations of the specification it contains.

9. Revision Information

XXX RFC-Ed please remove this section prior to publication.

Revision 00 was the first WG draft.

Revision 01 includes updates to complete all the sections and a rewrite to improve readability. Added section 2. Author list reversed, since Gorry has become the lead author. Corrections following feedback from Wes Eddy upon review of an interim version of this draft.

Note: Wes Eddy raised a question about whether discussion of the ECN Pitfalls could be improved or restructured - this is expected to be addressed in the next revision.

Revision 02 updates the title, and also the description of mechanisms that help with partial ECN support.

We think this draft is ready for wider review. Comments are welcome to the authors or via the IETF AQM or TSVWG mailing lists.

Revision 03 includes updates from the mailing list and WG discussions at the Dallas IETF meeting.

The section "Avoiding Capacity Overshoot" was removed, since this refers primarily to an AQM benefit, and the additional benefits of ECN are already stated. Separated normative and informative references

Revision 04 (WG Review during WGLC)

Updated the abstract.

Added a table of contents.

Addressed various (some conflicting) comments during WGLC with new text.

The section on Network Support for ECN was moved, and some suggestions for rewording sections were implemented.

Decided not to remove section headers for 2.1 and 2.2 - to ensure the document clearly calls-out the benefits.

Updated references. Updated text to improve consistency of terms and added definitions for key terms.

Note: The group suggested this document should not define recommendations for end hosts or routers, but simply state the things needs to enable deployment to be successful.

Revision 05 (after WGLC comments)

Updated abstract to avoid suggesting that this describes new methods for deployment.

Added ECN-field definition, and sorted terms in order.

Added an opening para to each "benefit" to say what this is. Sought to remove redundancy between sections.

Added new section on Codepoints to avoid saying the same thing twice.

Reworked sections 3 and 4 to clarify discussion and to remove unnecessary text.

Reformatted Summary to refer to sections describing things, rather than appear as a list of new recommendations. Reordered to match the new document order.

Note: This version expects an update to RFC5405.bis that will indicate UDP ECN requirements (normative).

Revision 06

Corrections from Miria.

Revision 07

Update to include IESG feedback from: Spencer, Dan, Benoit, Joel. Corrected Non-ECN to Not-ECN where appropriate, added table of codepoints, clarified sentences describing "conservative" behaviour, added requirement to not do ToS-based routing (Junos enhanced hash), etc. Ammended Acknowledgments section.

Revision 08

Typo and definition correction from Bob Briscoe.

AQM Characterization Guidelines
draft-ietf-aqm-eval-guidelines-13

Abstract

Unmanaged large buffers in today's networks have given rise to a slew of performance issues. These performance issues can be addressed by some form of Active Queue Management (AQM) mechanism, optionally in combination with a packet scheduling scheme such as fair queuing. This document describes various criteria for performing characterizations of AQM schemes, that can be used in lab testing during development, prior to deployment.

Status of This Memo

This Internet-Draft is submitted in full conformance with the provisions of BCP 78 and BCP 79.

Internet-Drafts are working documents of the Internet Engineering Task Force (IETF). Note that other groups may also distribute working documents as Internet-Drafts. The list of current Internet-Drafts is at <http://datatracker.ietf.org/drafts/current/>.

Internet-Drafts are draft documents valid for a maximum of six months and may be updated, replaced, or obsoleted by other documents at any time. It is inappropriate to use Internet-Drafts as reference material or to cite them other than as "work in progress."

This Internet-Draft will expire on December 16, 2016.

1. Introduction

Active Queue Management (AQM) addresses the concerns arising from using unnecessarily large and unmanaged buffers to improve network and application performance, such as presented in the section 1.2 of the AQM recommendations document [RFC7567]. Several AQM algorithms have been proposed in the past years, most notably Random Early Detection (RED) [FLOY1993], BLUE [FENG2002], and Proportional Integral controller (PI) [HOLLO2001], and more recently CoDel [I-D.ietf-aqm-codel] and PIE [I-D.ietf-aqm-pie]. In general, these algorithms actively interact with the Transmission Control Protocol (TCP) and any other transport protocol that deploys a congestion

control scheme to manage the amount of data they keep in the network. The available buffer space in the routers and switches should be large enough to accommodate the short-term buffering requirements. AQM schemes aim at reducing buffer occupancy, and therefore the end-to-end delay. Some of these algorithms, notably RED, have also been widely implemented in some network devices. However, the potential benefits of the RED scheme have not been realized since RED is reported to be usually turned off.

A buffer is a physical volume of memory in which a queue or set of queues are stored. When speaking of a specific queue in this document, "buffer occupancy" refers to the amount of data (measured in bytes or packets) that are in the queue, and the "maximum buffer size" refers to the maximum buffer occupancy. In switches and routers, a global memory space is often shared between the available interfaces, and thus, the maximum buffer size for any given interface may vary over the time.

Bufferbloat [BB2011] is the consequence of deploying large unmanaged buffers on the Internet -- the buffering has often been measured to be ten times or hundred times larger than needed. Large buffer sizes in combination with TCP and/or unresponsive flows increases end-to-end delay. This results in poor performance for latency-sensitive applications such as real-time multimedia (e.g., voice, video, gaming, etc). The degree to which this affects modern networking equipment, especially consumer-grade equipment's, produces problems even with commonly used web services. Active queue management is thus essential to control queuing delay and decrease network latency.

The Active Queue Management and Packet Scheduling Working Group (AQM WG) was chartered to address the problems with large unmanaged buffers in the Internet. Specifically, the AQM WG is tasked with standardizing AQM schemes that not only address concerns with such buffers, but also are robust under a wide variety of operating conditions. This document provides characterization guidelines that can be used to assess the applicability, performance and deployability of an AQM, whether it is candidate for standardization at IETF or not.

AQM algorithm implemented in a router can be separated from the scheduling of packets sent out by the router as discussed in the AQM recommendations document [RFC7567]. The rest of this memo refers to the AQM as a dropping/marketing policy as a separate feature to any interface scheduling scheme. This document may be complemented with another one on guidelines for assessing combination of packet scheduling and AQM. We note that such a document will inherit all the guidelines from this document plus any additional scenarios

relevant for packet scheduling such as flow starvation evaluation or impact of the number of hash buckets.

1.1. Reducing the latency and maximizing the goodput

The trade-off between reducing the latency and maximizing the goodput is intrinsically linked to each AQM scheme and is key to evaluating its performance. To ensure the safety deployment of an AQM, its behaviour should be assessed in a variety of scenarios. Whenever possible, solutions ought to aim at both maximizing goodput and minimizing latency.

1.2. Goals of this document

This document recommends a generic list of scenarios against which an AQM proposal should be evaluated, considering both potential performance gain and safety of deployment. The guidelines help to quantify performance of AQM schemes in terms of latency reduction, goodput maximization and the trade-off between these two. The document presents central aspects of an AQM algorithm that should be considered whatever the context, such as burst absorption capacity, RTT fairness or resilience to fluctuating network conditions. The guidelines also discuss methods to understand the various aspects associated with safely deploying and operating the AQM scheme. Thus, one of the key objectives behind formulating the guidelines is to help ascertain whether a specific AQM is not only better than drop-tail (i.e. without AQM and with a BDP-sized buffer) but also safe to deploy: the guidelines can be used to compare several AQM proposals with each other, but should be used to compare a proposal with drop-tail.

This memo details generic characterization scenarios against which any AQM proposal should be evaluated, irrespective of whether or not an AQM is standardized by the IETF. This documents recommends the relevant scenarios and metrics to be considered. The document presents central aspects of an AQM algorithm that should be considered whatever the context, such as burst absorption capacity, RTT fairness or resilience to fluctuating network conditions.

These guidelines do not define and are not bound to a particular deployment scenario or evaluation toolset. Instead the guidelines can be used to assert the potential gain of introducing an AQM for the particular environment, which is of interest to the testers. These guidelines do not cover every possible aspect of a particular algorithm. These guidelines do not present context-dependent scenarios (such as 802.11 WLANs, data-centers or rural broadband networks). To keep the guidelines generic, a number of potential router components and algorithms (such as DiffServ) are omitted.

The goals of this document can thus be summarized as follows:

- o The present characterization guidelines provide a non-exhaustive list of scenarios to help ascertain whether an AQM is not only better than drop-tail (with a BDP-sized buffer), but also safe to deploy; the guidelines can also be used to compare several AQM proposals with each other.
- o The present characterization guidelines (1) are not bound to a particular evaluation toolset and (2) can be used for various deployment contexts; testers are free to select a toolset that is best suited for the environment in which their proposal will be deployed.
- o The present characterization guidelines are intended to provide guidance for better selecting an AQM for a specific environment; it is not required that an AQM proposal is evaluated following these guidelines for its standardization.

1.3. Requirements Language

The key words "MUST", "MUST NOT", "REQUIRED", "SHALL", "SHALL NOT", "SHOULD", "SHOULD NOT", "RECOMMENDED", "MAY", and "OPTIONAL" in this document are to be interpreted as described in RFC 2119 [RFC2119].

1.4. Glossary

- o application-limited traffic: a type of traffic that does not have an unlimited amount of data to transmit.
- o AQM: the Active Queue Management (AQM) algorithm implemented in a router can be separated from the scheduling of packets sent by the router. The rest of this memo refers to the AQM as a dropping/marking policy as a separate feature to any interface scheduling scheme [RFC7567].
- o BDP: Bandwidth Delay Product.
- o buffer: a physical volume of memory in which a queue or set of queues are stored.
- o buffer occupancy: amount of data that are stored in a buffer, measured in bytes or packets.
- o buffer size: maximum buffer occupancy, that is the maximum amount of data that may be stored in a buffer, measured in bytes or packets.

- o IW10: TCP initial congestion window set to 10 packets.
- o latency: one-way delay of packets across Internet paths. This definition suits transport layer definition of the latency, that shall not be confused with an application layer view of the latency.
- o goodput: goodput is defined as the number of bits per unit of time forwarded to the correct destination minus any bits lost or retransmitted [RFC2647]. The goodput should be determined for each flow and not for aggregates of flows.
- o SQRT: the square root function.
- o ROUND: the round function.

2. End-to-end metrics

End-to-end delay is the result of propagation delay, serialization delay, service delay in a switch, medium-access delay and queuing delay, summed over the network elements along the path. AQM schemes may reduce the queuing delay by providing signals to the sender on the emergence of congestion, but any impact on the goodput must be carefully considered. This section presents the metrics that could be used to better quantify (1) the reduction of latency, (2) maximization of goodput and (3) the trade-off between these two. This section provides normative requirements for metrics that can be used to assess the performance of an AQM scheme.

Some metrics listed in this section are not suited to every type of traffic detailed in the rest of this document. It is therefore not necessary to measure all of the following metrics: the chosen metric may not be relevant to the context of the evaluation scenario (e.g., latency vs. goodput trade-off in application-limited traffic scenarios). Guidance is provided for each metric.

2.1. Flow completion time

The flow completion time is an important performance metric for the end-user when the flow size is finite. The definition of the flow size may be source of contradictions, thus, this metric can consider a flow as a single file. Considering the fact that an AQM scheme may drop/mark packets, the flow completion time is directly linked to the dropping/marking policy of the AQM scheme. This metric helps to better assess the performance of an AQM depending on the flow size. The Flow Completion Time (FCT) is related to the flow size (Fs) and the goodput for the flow (G) as follows:

$$FCT [s] = F_s [Byte] / (G [Bit/s] / 8 [Bit/Byte])$$

Where flow size is the size of the transport-layer payload in bits and goodput is the transport-layer payload transfer time (described in Section 2.5).

If this metric is used to evaluate the performance of web transfers, it is suggested to rather consider the time needed to download all the objects that compose the web page, as this makes more sense in terms of user experience than assessing the time needed to download each object.

2.2. Flow start up time

The flow start up time is the time between the request has been sent from the client and the server starts to transmit data. The amount of packets dropped by an AQM may seriously affect the waiting period during which the data transfer has not started. This metric would specifically focus on the operations such as DNS lookups, TCP opens and SSL handshakes.

2.3. Packet loss

Packet loss can occur en-route, this can impact the end-to-end performance measured at receiver.

The tester should evaluate loss experienced at the receiver using one of the two metrics:

- o the packet loss ratio: this metric is to be frequently measured during the experiment. The long-term loss ratio is of interest for steady-state scenarios only;
- o the interval between consecutive losses: the time between two losses is to be measured.

The packet loss ratio can be assessed by simply evaluating the loss ratio as a function of the number of lost packets and the total number of packets sent. This might not be easily done in laboratory testing, for which these guidelines advice the tester:

- o to check that for every packet, a corresponding packet was received within a reasonable time, as presented in the document that proposes a metric for one-way packet loss across Internet paths [RFC2680].

- o to keep a count of all packets sent, and a count of the non-duplicate packets received, as discussed in RFC that presents a benchmarking methodology [RFC2544].

The interval between consecutive losses, which is also called a gap, is a metric of interest for VoIP traffic [RFC3611].

2.4. Packet loss synchronization

One goal of an AQM algorithm is to help to avoid global synchronization of flows sharing a bottleneck buffer on which the AQM operates ([RFC2309],[RFC7567]). The "degree" of packet-loss synchronization between flows should be assessed, with and without the AQM under consideration.

Loss synchronization among flows may be quantified by several slightly different metrics that capture different aspects of the same issue [HASS2008]. However, in real-world measurements the choice of metric could be imposed by practical considerations -- e.g., whether fine-grained information on packet losses at the bottleneck is available or not. For the purpose of AQM characterization, a good candidate metric is the global synchronization ratio, measuring the proportion of flows losing packets during a loss event. This metric can be used in real-world experiments to characterize synchronization along arbitrary Internet paths [JAY2006].

If an AQM scheme is evaluated using real-life network environments, it is worth pointing out that some network events, such as failed link restoration may cause synchronized losses between active flows and thus confuse the meaning of this metric.

2.5. Goodput

The goodput has been defined as the number of bits per unit of time forwarded to the correct destination interface, minus any bits lost or retransmitted, such as proposed in the section 3.17 of the RFC describing the benchmarking terminology for firewall performances [RFC2647]. This definition requires that the test setup needs to be qualified to assure that it is not generating losses on its own.

Measuring the end-to-end goodput provides an appreciation of how well an AQM scheme improves transport and application performance. The measured end-to-end goodput is linked to the dropping/marketing policy of the AQM scheme -- e.g., the fewer the number of packet drops, the fewer packets need retransmission, minimizing the impact of AQM on transport and application performance. Additionally, an AQM scheme may resort to Explicit Congestion Notification (ECN) marking as an initial means to control delay. Again, marking packets instead of

dropping them reduces the number of packet retransmissions and increases goodput. End-to-end goodput values help to evaluate the AQM scheme's effectiveness of an AQM scheme in minimizing packet drops that impact application performance and to estimate how well the AQM scheme works with ECN.

The measurement of the goodput allows the tester to evaluate to which extent an AQM is able to maintain a high bottleneck utilization. This metric should also be obtained frequently during an experiment as the long-term goodput is relevant for steady-state scenarios only and may not necessarily reflect how the introduction of an AQM actually impacts the link utilization during at a certain period of time. Fluctuations in the values obtained from these measurements may depend on other factors than the introduction of an AQM, such as link layer losses due to external noise or corruption, fluctuating bandwidths (802.11 WLANs), heavy congestion levels or transport layer's rate reduction by congestion control mechanism.

2.6. Latency and jitter

The latency, or the one-way delay metric, is discussed in [RFC2679]. There is a consensus on an adequate metric for the jitter, that represents the one-way delay variations for packets from the same flow: the Packet Delay Variation (PDV) serves well all use cases [RFC5481].

The end-to-end latency includes components other than just the queuing delay, such as the signal processing delay, transmission delay and the processing delay. Moreover, the jitter is caused by variations in queuing and processing delay (e.g., scheduling effects). The introduction of an AQM scheme would impact end-to-end latency and jitter, and therefore these metrics should be considered in the end-to-end evaluation of performance.

2.7. Discussion on the trade-off between latency and goodput

The metrics presented in this section may be considered in order to discuss and quantify the trade-off between latency and goodput.

With regards to the goodput, and in addition to the long-term stationary goodput value, it is recommended to take measurements every multiple of the minimum RTT (minRTT) between A and B. It is suggested to take measurements at least every $K \times \text{minRTT}$ (to smooth out the fluctuations), with $K=10$. Higher values for K can be considered whenever it is more appropriate for the presentation of the results, since the value for K may depend on the network's path characteristics. The measurement period must be disclosed for each experiment and when results/values are compared across different AQM

schemes, the comparisons should use exactly the same measurement periods. With regards to latency, it is recommended to take the samples on per-packet basis whenever possible depending on the features provided by hardware/software and the impact of sampling itself on the hardware performance.

From each of these sets of measurements, the cumulative density function (CDF) of the considered metrics should be computed. If the considered scenario introduces dynamically varying parameters, temporal evolution of the metrics could also be generated. For each scenario, the following graph may be generated: the x-axis shows queuing delay (that is the average per-packet delay in excess of minimum RTT), the y-axis the goodput. Ellipses are computed such as detailed in [WINS2014]: "We take each individual [...] run [...] as one point, and then compute the 1-epsilon elliptic contour of the maximum-likelihood 2D Gaussian distribution that explains the points. [...] we plot the median per-sender throughput and queuing delay as a circle. [...] The orientation of an ellipse represents the covariance between the throughput and delay measured for the protocol." This graph provides part of a better understanding of (1) the delay/goodput trade-off for a given congestion control mechanism (Section 5), and (2) how the goodput and average queue delay vary as a function of the traffic load (Section 8.2).

3. Generic setup for evaluations

This section presents the topology that can be used for each of the following scenarios, the corresponding notations and discusses various assumptions that have been made in the document.

3.1. Topology and notations

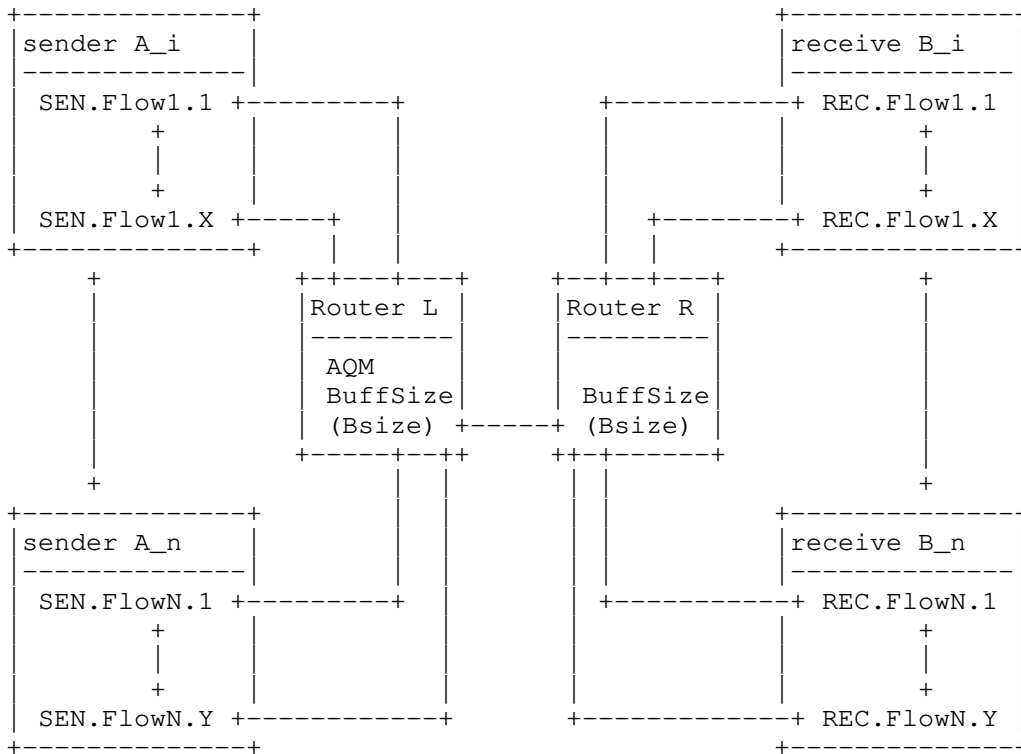

Figure 1: Topology and notations

Figure 1 is a generic topology where:

- o traffic profile is a set of flows with similar characteristics - RTT, congestion control scheme, transport protocol, etc.;
- o senders with different traffic characteristics (i.e., traffic profiles) can be introduced;
- o the timing of each flow could be different (i.e., when does each flow start and stop);
- o each traffic profile can comprise various number of flows;
- o each link is characterized by a couple (one-way delay, capacity);
- o sender A_i is instantiated for each traffic profile. A corresponding receiver B_i is instantiated for receiving the flows in the profile;

- o flows sharing a bottleneck (the link between routers L and R);
- o the tester should consider both scenarios of asymmetric and symmetric bottleneck links in terms of bandwidth. In case of asymmetric link, the capacity from senders to receivers is higher than the one from receivers to senders; the symmetric link scenario provides a basic understanding of the operation of the AQM mechanism whereas the asymmetric link scenario evaluates an AQM mechanism in a more realistic setup;
- o in asymmetric link scenarios, the tester should study the bi-directional traffic between A and B (downlink and uplink) with the AQM mechanism deployed on one direction only. The tester may additionally consider a scenario with AQM mechanism being deployed on both directions. In each scenario, the tester should investigate the impact of drop policy of the AQM on TCP ACK packets and its impact on the performance (Section 9.2).

Although this topology may not perfectly reflect actual topologies, the simple topology is commonly used in the world of simulations and small testbeds. It can be considered as adequate to evaluate AQM proposals [I-D.irtf-iccr-g-tcpeval]. Testers ought to pay attention to the topology that has been used to evaluate an AQM scheme when comparing this scheme with a newly proposed AQM scheme.

3.2. Buffer size

The size of the buffers should be carefully chosen, and may be set to the bandwidth-delay product; the bandwidth being the bottleneck capacity and the delay the largest RTT in the considered network. The size of the buffer can impact the AQM performance and is a dimensioning parameter that will be considered when comparing AQM proposals.

If a specific buffer size is required, the tester must justify and detail the way the maximum queue size is set. Indeed, the maximum size of the buffer may affect the AQM's performance and its choice should be elaborated for a fair comparison between AQM proposals. While comparing AQM schemes the buffer size should remain the same across the tests.

3.3. Congestion controls

This document considers running three different congestion control algorithms between A and B

- o Standard TCP congestion control: the base-line congestion control is TCP NewReno with SACK [RFC5681].

- o Aggressive congestion controls: a base-line congestion control for this category is TCP Cubic [I-D.ietf-tcpm-cubic].
- o Less-than Best Effort (LBE) congestion controls: an LBE congestion control 'results in smaller bandwidth and/or delay impact on standard TCP than standard TCP itself, when sharing a bottleneck with it.': a base-line congestion control for this category is LEDBAT [RFC6817].

Other transport congestion controls can OPTIONALLY be evaluated in addition. Recent transport layer protocols are not mentioned in the following sections, for the sake of simplicity.

4. Methodology, Metrics, AQM Comparisons, Packet Sizes, Scheduling and ECN

4.1. Methodology

A description of each test setup should be detailed to allow this test to be compared with other tests. This also allows others to replicate the tests if needed. This test setup should detail software and hardware versions. The tester could make its data available.

The proposals should be evaluated on real-life systems, or they may be evaluated with event-driven simulations (such as ns-2, ns-3, OMNET, etc). The proposed scenarios are not bound to a particular evaluation toolset.

The tester is encouraged to make the detailed test setup and the results publicly available.

4.2. Comments on metrics measurement

The document presents the end-to-end metrics that ought to be used to evaluate the trade-off between latency and goodput in Section 2. In addition to the end-to-end metrics, the queue-level metrics (normally collected at the device operating the AQM) provide a better understanding of the AQM behavior under study and the impact of its internal parameters. Whenever it is possible (e.g., depending on the features provided by the hardware/software), these guidelines advise to consider queue-level metrics, such as link utilization, queuing delay, queue size or packet drop/mark statistics in addition to the AQM-specific parameters. However, the evaluation must be primarily based on externally observed end-to-end metrics.

These guidelines do not aim to detail on the way these metrics can be measured, since the way these metrics are measured is expected to depend on the evaluation toolset.

4.3. Comparing AQM schemes

This document recognizes that these guidelines may be used for comparing AQM schemes.

AQM schemes need to be compared against both performance and deployment categories. In addition, this section details how best to achieve a fair comparison of AQM schemes by avoiding certain pitfalls.

4.3.1. Performance comparison

AQM schemes should be compared against the generic scenarios that are summarized in Section 13. AQM schemes may be compared for specific network environments such as data centers, home networks, etc. If an AQM scheme has parameter(s) that were externally tuned for optimization or other purposes, these values must be disclosed.

AQM schemes belong to different varieties such as queue-length based schemes (ex. RED) or queueing-delay based scheme (ex. CoDel, PIE). AQM schemes expose different control knobs associated with different semantics. For example, while both PIE and CoDel are queueing-delay based schemes and each expose a knob to control the queueing delay -- PIE's "queueing delay reference" vs. CoDel's "queueing delay target", the two tuning parameters of the two schemes have different semantics, resulting in different control points. Such differences in AQM schemes can be easily overlooked while making comparisons.

This document recommends the following procedures for a fair performance comparison between the AQM schemes:

1. similar control parameters and implications: Testers should be aware of the control parameters of the different schemes that control similar behavior. Testers should also be aware of the input value ranges and corresponding implications. For example, consider two different schemes - (A) queue-length based AQM scheme, and (B) queueing-delay based scheme. A and B are likely to have different kinds of control inputs to control the target delay - target queue length in A vs. target queuing delay in B, for example. Setting parameter values such as 100MB for A vs. 10ms for B will have different implications depending on evaluation context. Such context-dependent implications must be considered before drawing conclusions on performance comparisons. Also, it would be preferable if an AQM proposal listed such

parameters and discussed how each relates to network characteristics such as capacity, average RTT etc.

2. compare over a range of input configurations: there could be situations when the set of control parameters that affect a specific behavior have different semantics between the two AQM schemes. As mentioned above, PIE has tuning parameters to control queue delay that has a different semantics from those used in CoDel. In such situations, these schemes need to be compared over a range of input configurations. For example, compare PIE vs. CoDel over the range of target delay input configurations.

4.3.2. Deployment comparison

AQM schemes must be compared against deployment criteria such as the parameter sensitivity (Section 8.3), auto-tuning (Section 12) or implementation cost (Section 11).

4.4. Packet sizes and congestion notification

An AQM scheme may be considering packet sizes while generating congestion signals [RFC7141]. For example, control packets such as DNS requests/responses, TCP SYN/ACKs are small, but their loss can severely impact application performance. An AQM scheme may therefore be biased towards small packets by dropping them with lower probability compared to larger packets. However, such an AQM scheme is unfair to data senders generating larger packets. Data senders, malicious or otherwise, are motivated to take advantage of such AQM scheme by transmitting smaller packets, and could result in unsafe deployments and unhealthy transport and/or application designs.

An AQM scheme should adhere to the recommendations outlined in the best current practice for dropping and marking packets document [RFC7141], and should not provide undue advantage to flows with smaller packets, such as discussed in the section 4.4 of the AQM recommendation document [RFC7567]. In order to evaluate if an AQM scheme is biased towards flows with smaller size packets, traffic can be generated, such as defined in Section 8.2.2, where half of the flows have smaller packets (e.g. 500 bytes packets) than the other half of the flow (e.g. 1500 bytes packets). In this case, the metrics reported could be the same as in Section 6.3, where Category I is the set of flows with smaller packets and Category II the one with larger packets. The bidirectional scenario could also be considered (Section 9.2).

4.5. Interaction with ECN

ECN [RFC3168] is an alternative that allows AQM schemes to signal receivers about network congestion that does not use packet drop. There are benefits of providing ECN support for an AQM scheme [WELZ2015].

If the tested AQM scheme can support ECN, the testers must discuss and describe the support of ECN, such as discussed in the AQM recommendation [RFC7567]. Also, the AQM's ECN support can be studied and verified by replicating tests in Section 8.1 with ECN turned ON at the TCP senders. The results can be used to not only evaluate the performance of the tested AQM with and without ECN markings, but also quantify the interest of enabling ECN.

4.6. Interaction with Scheduling

A network device may use per-flow or per-class queuing with a scheduling algorithm to either prioritize certain applications or classes of traffic, limit the rate of transmission, or to provide isolation between different traffic flows within a common class, such as discussed in the section 2.1 of the AQM recommendation document [RFC7567].

The scheduling and the AQM conjointly impact on the end-to-end performance. Therefore, the AQM proposal must discuss the feasibility to add scheduling combined with the AQM algorithm. It can be explained whether the dropping policy is applied when packets are being enqueued or dequeued.

These guidelines do not propose guidelines to assess the performance of scheduling algorithms. Indeed, as opposed to characterizing AQM schemes that is related to their capacity to control the queuing delay in a queue, characterizing scheduling schemes is related to the scheduling itself and its interaction with the AQM scheme. As one example, the scheduler may create sub-queues and the AQM scheme may be applied on each of the sub-queues, and/or the AQM could be applied on the whole queue. Also, schedulers might, such as FQ-CoDel [HOEI2015] or FavorQueue [ANEL2014], introduce flow prioritization. In these cases, specific scenarios should be proposed to ascertain that these scheduler schemes not only helps in tackling the bufferbloat, but also are robust under a wide variety of operating conditions. This is out of the scope of this document that focus on dropping and/or marking AQM schemes.

5. Transport Protocols

Network and end-devices need to be configured with a reasonable amount of buffer space to absorb transient bursts. In some situations, network providers tend to configure devices with large buffers to avoid packet drops triggered by a full buffer and to maximize the link utilization for standard loss-based TCP traffic.

AQM algorithms are often evaluated by considering Transmission Control Protocol (TCP) [RFC0793] with a limited number of applications. TCP is a widely deployed transport. It fills up available buffers until a sender transferring a bulk flow with TCP receives a signal (packet drop) that reduces the sending rate. The larger the buffer, the higher the buffer occupancy, and therefore the queuing delay. An efficient AQM scheme sends out early congestion signals to TCP to bring the queuing delay under control.

Not all endpoints (or applications) using TCP use the same flavor of TCP. Variety of senders generate different classes of traffic which may not react to congestion signals (aka non-responsive flows in the section 3 of the AQM recommendation document [RFC7567]) or may not reduce their sending rate as expected (aka Transport Flows that are less responsive than TCP, such as proposed in the section 3 of the AQM recommendation document [RFC7567], also called "aggressive flows"). In these cases, AQM schemes seek to control the queuing delay.

This section provides guidelines to assess the performance of an AQM proposal for various traffic profiles -- different types of senders (with different TCP congestion control variants, unresponsive, aggressive).

5.1. TCP-friendly sender

5.1.1. TCP-friendly sender with the same initial congestion window

This scenario helps to evaluate how an AQM scheme reacts to a TCP-friendly transport sender. A single long-lived, non application-limited, TCP NewReno flow, with an Initial congestion Window (IW) set to 3 packets, transfers data between sender A and receiver B. Other TCP friendly congestion control schemes such as TCP-friendly rate control [RFC5348] etc may also be considered.

For each TCP-friendly transport considered, the graph described in Section 2.7 could be generated.

5.1.2. TCP-friendly sender with different initial congestion windows

This scenario can be used to evaluate how an AQM scheme adapts to a traffic mix consisting of TCP flows with different values of the IW.

For this scenario, two types of flows must be generated between sender A and receiver B:

- o A single long-lived non application-limited TCP NewReno flow;
- o A single application-limited TCP NewReno flow, with an IW set to 3 or 10 packets. The size of the data transferred must be strictly higher than 10 packets and should be lower than 100 packets.

The transmission of the non application-limited flow must start first and the transmission of the application-limited flow starts after the non application-limited flow has reached steady state. The steady state can be assumed when the goodput is stable.

For each of these scenarios, the graph described in Section 2.7 could be generated for each class of traffic (application-limited and non application-limited). The completion time of the application-limited TCP flow could be measured.

5.2. Aggressive transport sender

This scenario helps testers to evaluate how an AQM scheme reacts to a transport sender that is more aggressive than a single TCP-friendly sender. We define 'aggressiveness' as a higher increase factor than standard upon a successful transmission and/or a lower than standard decrease factor upon a unsuccessful transmission (e.g., in case of congestion controls with Additive-Increase Multiplicative-Decrease (AIMD) principle, a larger AI and/or MD factors). A single long-lived, non application-limited, TCP Cubic flow transfers data between sender A and receiver B. Other aggressive congestion control schemes may also be considered.

For each flavor of aggressive transports, the graph described in Section 2.7 could be generated.

5.3. Unresponsive transport sender

This scenario helps testers to evaluate how an AQM scheme reacts to a transport sender that is less responsive than TCP. Note that faulty transport implementations on an end host and/or faulty network elements en-route that "hide" congestion signals in packet headers may also lead to a similar situation, such that the AQM scheme needs to adapt to unresponsive traffic (see the section 3 of the AQM

recommendation document [RFC7567]). To this end, these guidelines propose the two following scenarios.

The first scenario can be used to evaluate queue build up. It considers unresponsive flow(s) whose sending rate is greater than the bottleneck link capacity between routers L and R. This scenario consists of a long-lived non application limited UDP flow transmits data between sender A and receiver B. Graphs described in Section 2.7 could be generated.

The second scenario can be used to evaluate if the AQM scheme is able to keep the responsive fraction under control. This scenario considers a mixture of TCP-friendly and unresponsive traffics. It consists of a long-lived UDP flow from unresponsive application and a single long-lived, non application-limited (unlimited data available to the transport sender from application layer), TCP New Reno flow that transmit data between sender A and receiver B. As opposed to the first scenario, the rate of the UDP traffic should not be greater than the bottleneck capacity, and should be higher than half of the bottleneck capacity. For each type of traffic, the graph described in Section 2.7 could be generated.

5.4. Less-than Best Effort transport sender

This scenario helps to evaluate how an AQM scheme reacts to LBE congestion controls that 'results in smaller bandwidth and/or delay impact on standard TCP than standard TCP itself, when sharing a bottleneck with it.' [RFC6297]. There are potential fateful interactions when AQM and LBE techniques are combined [GONG2014]; this scenario helps to evaluate whether the coexistence of the proposed AQM and LBE techniques may be possible.

A single long-lived non application-limited TCP NewReno flow transfers data between sender A and receiver B. Other TCP-friendly congestion control schemes may also be considered. Single long-lived non application-limited LEDBAT [RFC6817] flows transfer data between sender A and receiver B. We recommend to set the target delay and gain values of LEDBAT respectively to 5 ms and 10 [TRAN2014]. Other LBE congestion control schemes may also be considered and are listed in the IETF survey of LBE protocols [RFC6297].

For each of the TCP-friendly and LBE transports, the graph described in Section 2.7 could be generated.

6. Round Trip Time Fairness

6.1. Motivation

An AQM scheme's congestion signals (via drops or ECN marks) must reach the transport sender so that a responsive sender can initiate its congestion control mechanism and adjust the sending rate. This procedure is thus dependent on the end-to-end path RTT. When the RTT varies, the onset of congestion control is impacted, and in turn impacts the ability of an AQM scheme to control the queue. It is therefore important to assess the AQM schemes for a set of RTTs between A and B (e.g., from 5 ms to 200 ms).

The asymmetry in terms of difference in intrinsic RTT between various paths sharing the same bottleneck should be considered, so that the fairness between the flows can be discussed. In this scenario, a flow traversing on shorter RTT path may react faster to congestion and recover faster from it compared to another flow on a longer RTT path. The introduction of AQM schemes may potentially improve the RTT fairness.

Introducing an AQM scheme may cause the unfairness between the flows, even if the RTTs are identical. This potential unfairness should be investigated as well.

6.2. Recommended tests

The recommended topology is detailed in Figure 1.

To evaluate the RTT fairness, for each run, two flows are divided into two categories. Category I whose RTT between sender A and receiver B should be 100ms. Category II which RTT between sender A and receiver B should be in the range [5ms;560ms] inclusive. The maximum value for the RTT represents the RTT of a satellite link [RFC2488].

A set of evaluated flows must use the same congestion control algorithm: all the generated flows could be single long-lived non application-limited TCP NewReno flows.

6.3. Metrics to evaluate the RTT fairness

The outputs that must be measured are: (1) the cumulative average goodput of the flow from Category I, `goodput_Cat_I` (Section 2.5); (2) the cumulative average goodput of the flow from Category II, `goodput_Cat_II` (Section 2.5); (3) the ratio `goodput_Cat_II/goodput_Cat_I`; (4) the average packet drop rate for each category (Section 2.3).

7. Burst Absorption

"AQM mechanisms need to control the overall queue sizes, to ensure that arriving bursts can be accommodated without dropping packets" [RFC7567].

7.1. Motivation

An AQM scheme can face bursts of packet arrivals due to various reasons. Dropping one or more packets from a burst can result in performance penalties for the corresponding flows, since dropped packets have to be retransmitted. Performance penalties can result in failing to meet SLAs and be a disincentive to AQM adoption.

The ability to accommodate bursts translates to larger queue length and hence more queuing delay. On the one hand, it is important that an AQM scheme quickly brings bursty traffic under control. On the other hand, a peak in the packet drop rates to bring a packet burst quickly under control could result in multiple drops per flow and severely impact transport and application performance. Therefore, an AQM scheme ought to bring bursts under control by balancing both aspects -- (1) queuing delay spikes are minimized and (2) performance penalties for ongoing flows in terms of packet drops are minimized.

An AQM scheme that maintains short queues allows some remaining space in the buffer for bursts of arriving packets. The tolerance to bursts of packets depends upon the number of packets in the queue, which is directly linked to the AQM algorithm. Moreover, an AQM scheme may implement a feature controlling the maximum size of accepted bursts, that can depend on the buffer occupancy or the currently estimated queuing delay. The impact of the buffer size on the burst allowance may be evaluated.

7.2. Recommended tests

For this scenario, tester must evaluate how the AQM performs with a traffic mixed that could be composed of (from sender A to receiver B):

- o Burst of packets at the beginning of a transmission, such as web traffic with IW10;
- o Applications that send large bursts of data, such as bursty video frames;
- o Background traffic, such as Constant Bit Rate (CBR) UDP traffic and/or A single non application-limited bulk TCP flow as background traffic.

Figure 2 presents the various cases for the traffic that must be generated between sender A and receiver B.

Case	Traffic Type			
	Video	Web (IW 10)	CBR	Bulk TCP Traffic
I	0	1	1	0
II	0	1	1	1
III	1	1	1	0
IV	1	1	1	1

Figure 2: Bursty traffic scenarios

A new web page download could start after the previous web page download is finished. Each web page could be composed by at least 50 objects and the size of each object should be at least 1kB. 6 TCP parallel connections should be generated to download the objects, each parallel connections having an initial congestion window set to 10 packets.

For each of these scenarios, the graph described in Section 2.7 could be generated for each application. Metrics such as end-to-end latency, jitter, flow completion time may be generated. For the cases of frame generation of bursty video traffic as well as the choice of web traffic pattern, these details and their presentation are left to the testers.

8. Stability

8.1. Motivation

The safety of an AQM scheme is directly related to its stability under varying operating conditions such as varying traffic profiles and fluctuating network conditions. Since operating conditions can vary often the AQM needs to remain stable under these conditions without the need for additional external tuning.

Network devices can experience varying operating conditions depending on factors such as time of the day, deployment scenario, etc. For example:

- o Traffic and congestion levels are higher during peak hours than off-peak hours.
- o In the presence of a scheduler, the draining rate of a queue can vary depending on the occupancy of other queues: a low load on a high priority queue implies a higher draining rate for the lower priority queues.
- o The capacity available can vary over time (e.g., a lossy channel, a link supporting traffic in a higher diffserv class).

Whether the target context is a not stable environment, the ability of an AQM scheme to maintain its control over the queuing delay and buffer occupancy can be challenged. This document proposes guidelines to assess the behavior of AQM schemes under varying congestion levels and varying draining rates.

8.2. Recommended tests

Note that the traffic profiles explained below comprises non application-limited TCP flows. For each of the below scenarios, the graphs described in Section 2.7 should be generated, and the goodput of the various flows should be cumulated. For Section 8.2.5 and Section 8.2.6 they should incorporate the results in per-phase basis as well.

Wherever the notion of time has explicitly mentioned in this subsection, time 0 starts from the moment all TCP flows have already reached their congestion avoidance phase.

8.2.1. Definition of the congestion Level

In these guidelines, the congestion levels are represented by the projected packet drop rate, had a drop-tail queue was chosen instead of an AQM scheme. When the bottleneck is shared among non application-limited TCP flows, l_r , the loss rate projection can be expressed as a function of N , the number of bulk TCP flows, and S , the sum of the bandwidth-delay product and the maximum buffer size, both expressed in packets, based on Eq. 3 of [MORR2000]:

$$l_r = 0.76 * N^2 / S^2$$

$$N = S * \text{SQRT}(1/0.76) * \text{SQRT}(l_r)$$

These guidelines use the loss rate to define the different congestion levels, but they do not stipulate that in other circumstances, measuring the congestion level gives you an accurate estimation of the loss rate or vice-versa.

8.2.2. Mild congestion

This scenario can be used to evaluate how an AQM scheme reacts to a light load of incoming traffic resulting in mild congestion -- packet drop rates around 0.1%. The number of bulk flows required to achieve this congestion level, N_{mild} , is then:

$$N_{\text{mild}} = \text{ROUND} (0.036 * S)$$

8.2.3. Medium congestion

This scenario can be used to evaluate how an AQM scheme reacts to incoming traffic resulting in medium congestion -- packet drop rates around 0.5%. The number of bulk flows required to achieve this congestion level, N_{med} , is then:

$$N_{\text{med}} = \text{ROUND} (0.081 * S)$$

8.2.4. Heavy congestion

This scenario can be used to evaluate how an AQM scheme reacts to incoming traffic resulting in heavy congestion -- packet drop rates around 1%. The number of bulk flows required to achieve this congestion level, N_{heavy} , is then:

$$N_{\text{heavy}} = \text{ROUND} (0.114 * S)$$

8.2.5. Varying the congestion level

This scenario can be used to evaluate how an AQM scheme reacts to incoming traffic resulting in various levels of congestion during the experiment. In this scenario, the congestion level varies within a large time-scale. The following phases may be considered: phase I - mild congestion during 0-20s; phase II - medium congestion during 20-40s; phase III - heavy congestion during 40-60s; phase I again, and so on.

8.2.6. Varying available capacity

This scenario can be used to help characterize how the AQM behaves and adapts to bandwidth changes. The experiments are not meant to reflect the exact conditions of Wi-Fi environments since it is hard to design repetitive experiments or accurate simulations for such scenarios.

To emulate varying draining rates, the bottleneck capacity between nodes 'Router L' and 'Router R' varies over the course of the experiment as follows:

- o Experiment 1: the capacity varies between two values within a large time-scale. As an example, the following phases may be considered: phase I - 100Mbps during 0-20s; phase II - 10Mbps during 20-40s; phase I again, and so on.
- o Experiment 2: the capacity varies between two values within a short time-scale. As an example, the following phases may be considered: phase I - 100Mbps during 0-100ms; phase II - 10Mbps during 100-200ms; phase I again, and so on.

The tester may choose a phase time-interval value different than what is stated above, if the network's path conditions (such as bandwidth-delay product) necessitate. In this case the choice of such time-interval value should be stated and elaborated.

The tester may additionally evaluate the two mentioned scenarios (short-term and long-term capacity variations), during and/or including TCP slow-start phase.

More realistic fluctuating capacity patterns may be considered. The tester may choose to incorporate realistic scenarios with regards to common fluctuation of bandwidth in state-of-the-art technologies.

The scenario consists of TCP NewReno flows between sender A and receiver B. To better assess the impact of draining rates on the AQM behavior, the tester must compare its performance with those of drop-tail and should provide a reference document for their proposal discussing performance and deployment compared to those of drop-tail. Burst traffic, such as presented in Section 7.2, could also be considered to assess the impact of varying available capacity on the burst absorption of the AQM.

8.3. Parameter sensitivity and stability analysis

The control law used by an AQM is the primary means by which the queuing delay is controlled. Hence understanding the control law is critical to understanding the behavior of the AQM scheme. The control law could include several input parameters whose values affect the AQM scheme's output behavior and its stability. Additionally, AQM schemes may auto-tune parameter values in order to maintain stability under different network conditions (such as different congestion levels, draining rates or network environments). The stability of these auto-tuning techniques is also important to understand.

Transports operating under the control of AQM experience the effect of multiple control loops that react over different timescales. It is therefore important that proposed AQM schemes are seen to be

stable when they are deployed at multiple points of potential congestion along an Internet path. The pattern of congestion signals (loss or ECN-marking) arising from AQM methods also need to not adversely interact with the dynamics of the transport protocols that they control.

AQM proposals should provide background material showing control theoretic analysis of the AQM control law and the input parameter space within which the control law operates as expected; or could use another way to discuss the stability of the control law. For parameters that are auto-tuned, the material should include stability analysis of the auto-tuning mechanism(s) as well. Such analysis helps to understand an AQM control law better and the network conditions/deployments under which the AQM is stable.

9. Various Traffic Profiles

This section provides guidelines to assess the performance of an AQM proposal for various traffic profiles such as traffic with different applications or bi-directional traffic.

9.1. Traffic mix

This scenario can be used to evaluate how an AQM scheme reacts to a traffic mix consisting of different applications such as:

- o Bulk TCP transfer
- o Web traffic
- o VoIP
- o Constant Bit Rate (CBR) UDP traffic
- o Adaptive video streaming (either unidirectional or bidirectional)

Various traffic mixes can be considered. These guidelines recommend to examine at least the following example: 1 bi-directional VoIP; 6 Web pages download (such as detailed in Section 7.2); 1 CBR; 1 Adaptive Video; 5 bulk TCP. Any other combinations could be considered and should be carefully documented.

For each scenario, the graph described in Section 2.7 could be generated for each class of traffic. Metrics such as end-to-end latency, jitter and flow completion time may be reported.

9.2. Bi-directional traffic

Control packets such as DNS requests/responses, TCP SYNs/ACKs are small, but their loss can severely impact the application performance. The scenario proposed in this section will help in assessing whether the introduction of an AQM scheme increases the loss probability of these important packets.

For this scenario, traffic must be generated in both downlink and uplink, such as defined in Section 3.1. The amount of asymmetry between the uplink and the downlink depends on the context. These guidelines recommend to consider a mild congestion level and the traffic presented in Section 8.2.2 in both directions. In this case, the metrics reported must be the same as in Section 8.2 for each direction.

The traffic mix presented in Section 9.1 may also be generated in both directions.

10. Example of multi-AQM scenario

10.1. Motivation

Transports operating under the control of AQM experience the effect of multiple control loops that react over different timescales. It is therefore important that proposed AQM schemes are seen to be stable when they are deployed at multiple points of potential congestion along an Internet path. The pattern of congestion signals (loss or ECN-marking) arising from AQM methods also need to not adversely interact with the dynamics of the transport protocols that they control.

10.2. Details on the evaluation scenario

Figure 3: Topology for the Multi-AQM scenario

Figure 3 describes topology options for evaluating multi-AQM scenarios. The AQM schemes are applied in sequence and impact the induced latency reduction, the induced goodput maximization and the trade-off between these two. Note that AQM schemes A and B introduced in Routers L and M could be (i) same scheme with identical parameter values, (ii) same scheme with different parameter values, or (iii) two different schemes. To best understand the interactions and implications, the mild congestion scenario as described in Section 8.2.2 is recommended such that the number of flows is equally shared among senders A and B. Other relevant combination of congestion levels could also be considered. We recommend to measure the metrics presented in Section 8.2.

11. Implementation cost

11.1. Motivation

Successful deployment of AQM is directly related to its cost of implementation. Network devices can need hardware or software implementations of the AQM mechanism. Depending on a device's capabilities and limitations, the device may or may not be able to implement some or all parts of their AQM logic.

AQM proposals should provide pseudo-code for the complete AQM scheme, highlighting generic implementation-specific aspects of the scheme such as "drop-tail" vs. "drop-head", inputs (e.g., current queuing delay, queue length), computations involved, need for timers, etc. This helps to identify costs associated with implementing the AQM scheme on a particular hardware or software device. This also facilitates discussions around which kind of devices can easily support the AQM and which cannot.

11.2. Recommended discussion

AQM proposals should highlight parts of their AQM logic that are device dependent and discuss if and how AQM behavior could be impacted by the device. For example, a queueing-delay based AQM scheme requires current queuing delay as input from the device. If the device already maintains this value, then it can be trivial to implement the their AQM logic on the device. If the device provides indirect means to estimate the queuing delay (for example: timestamps, dequeuing rate), then the AQM behavior is sensitive to the precision of the queuing delay estimations are for that device. Highlighting the sensitivity of an AQM scheme to queuing delay estimations helps implementers to identify appropriate means of implementing the mechanism on a device.

12. Operator Control and Auto-tuning

12.1. Motivation

One of the biggest hurdles of RED deployment was/is its parameter sensitivity to operating conditions -- how difficult it is to tune RED parameters for a deployment to achieve acceptable benefit from using RED. Fluctuating congestion levels and network conditions add to the complexity. Incorrect parameter values lead to poor performance.

Any AQM scheme is likely to have parameters whose values affect the control law and behaviour of an AQM. Exposing all these parameters as control parameters to a network operator (or user) can easily result in a unsafe AQM deployment. Unexpected AQM behavior ensues when parameter values are set improperly. A minimal number of control parameters minimizes the number of ways a user can break a system where an AQM scheme is deployed at. Fewer control parameters make the AQM scheme more user-friendly and easier to deploy and debug.

"AQM algorithms should not require tuning of initial or configuration parameters in common use cases." such as stated in the section 4.3 of the AQM recommendation document [RFC7567]. A scheme ought to expose only those parameters that control the macroscopic AQM behavior such as queue delay threshold, queue length threshold, etc.

Additionally, the safety of an AQM scheme is directly related to its stability under varying operating conditions such as varying traffic profiles and fluctuating network conditions, as described in Section 8. Operating conditions vary often and hence the AQM needs to remain stable under these conditions without the need for additional external tuning. If AQM parameters require tuning under these conditions, then the AQM must self-adapt necessary parameter values by employing auto-tuning techniques.

12.2. Recommended discussion

In order to understand an AQM's deployment considerations and performance under a specific environment, AQM proposals should describe the parameters that control the macroscopic AQM behavior, and identify any parameters that require tuning to operational conditions. It could be interesting to also discuss that even if an AQM scheme may not adequately auto-tune its parameters, the resulting performance may not be optimal, but close to something reasonable.

If there are any fixed parameters within the AQM, their setting should be discussed and justified, to help understand whether a fixed parameter value is applicable for a particular environment.

If an AQM scheme is evaluated with parameter(s) that were externally tuned for optimization or other purposes, these values must be disclosed.

13. Summary

Figure 4 lists the scenarios for an extended characterization of an AQM scheme. This table comes along with a set of requirements to present more clearly the weight and importance of each scenario. The requirements listed here are informational and their relevance may depend on the deployment scenario.

Scenario	Sec.	Informational requirement
Interaction with ECN	4.5	must be discussed if supported
Interaction with Scheduling	4.6	should be discussed
Transport Protocols	5.	
TCP-friendly sender	5.1	scenario must be considered
Aggressive sender	5.2	scenario must be considered
Unresponsive sender	5.3	scenario must be considered
LBE sender	5.4	scenario may be considered
Round Trip Time Fairness	6.2	scenario must be considered
Burst Absorption	7.2	scenario must be considered
Stability	8.	
Varying congestion levels	8.2.5	scenario must be considered
Varying available capacity	8.2.6	scenario must be considered
Parameters and stability	8.3	this should be discussed
Various Traffic Profiles	9.	
Traffic mix	9.1	scenario is recommended
Bi-directional traffic	9.2	scenario may be considered
Multi-AQM	10.2	Scenario may be considered

Figure 4: Summary of the scenarios and their requirements

14. Acknowledgements

This work has been partially supported by the European Community under its Seventh Framework Programme through the Reducing Internet Transport Latency (RITE) project (ICT-317700).

Many thanks to S. Akhtar, A.B. Bagayoko, F. Baker, R. Bless, D. Collier-Brown, G. Fairhurst, J. Gettys, P. Goltsman, T. Hoiland-Jorgensen, K. Kilkki, C. Kulatunga, W. Lautenschlager, A.C. Morton, R. Pan, G. Skinner, D. Taht and M. Welzl for detailed and wise feedback on this document.

15. IANA Considerations

This memo includes no request to IANA.

16. Security Considerations

Some security considerations for AQM are identified in [RFC7567]. This document, by itself, presents no new privacy nor security issues.

PIE: A Lightweight Control Scheme To Address the
Bufferbloat Problem

draft-ietf-aqm-pie-10

Abstract

Bufferbloat is a phenomenon in which excess buffers in the network cause high latency and latency variation. As more and more interactive applications (e.g. voice over IP, real time video streaming and financial transactions) run in the Internet, high latency and latency variation degrade application performance. There is a pressing need to design intelligent queue management schemes that can control latency and latency variation, and hence provide desirable quality of service to users.

This document presents a lightweight active queue management design, called PIE (Proportional Integral controller Enhanced), that can effectively control the average queueing latency to a target value. Simulation results, theoretical analysis and Linux testbed results have shown that PIE can ensure low latency and achieve high link utilization under various congestion situations. The design does not require per-packet timestamps, so it incurs very little overhead and is simple enough to implement in both hardware and software.

Status of this Memo

This Internet-Draft is submitted to IETF in full conformance with the provisions of BCP 78 and BCP 79.

Internet-Drafts are working documents of the Internet Engineering Task Force (IETF), its areas, and its working groups. Note that other groups may also distribute working documents as Internet-Drafts.

Internet-Drafts are draft documents valid for a maximum of six months and may be updated, replaced, or obsoleted by other documents at any

time. It is inappropriate to use Internet-Drafts as reference material or to cite them other than as "work in progress."

1. Introduction

The explosion of smart phones, tablets and video traffic in the Internet brings about a unique set of challenges for congestion control. To avoid packet drops, many service providers or data center operators require vendors to put in as much buffer as possible. Because of the rapid decrease in memory chip prices, these requests are easily accommodated to keep customers happy. While this solution succeeds in assuring low packet loss and high TCP throughput, it suffers from a major downside. The TCP protocol continuously increases its sending rate and causes network buffers to fill up. TCP cuts its rate only when it receives a packet drop or mark that is interpreted as a congestion signal. However, drops and marks usually occur when network buffers are full or almost full. As a result, excess buffers, initially designed to avoid packet drops, would lead to highly elevated queueing latency and latency variation. Designing a queue management scheme is a delicate balancing act: it not only should allow short-term burst to smoothly pass, but also should control the average latency in the presence of long-running greedy flows.

AQM schemes could potentially solve the aforementioned problem. Active queue management (AQM) schemes, such as Random Early Detection (RED [RED] as suggested in RFC 2309[RFC2309], now obsoleted by RFC 7567 [RFC7567]), have been around for well over a decade. RED is implemented in a wide variety of network devices, both in hardware and software. Unfortunately, due to the fact that RED needs careful tuning of its parameters for various network conditions, most network operators don't turn RED on. In addition, RED is designed to control the queue length which would affect latency implicitly. It does not control latency directly. Hence, the Internet today still lacks an effective design that can control buffer latency to improve the quality of experience to latency-sensitive applications. The more recent RFC 7567 calls for new methods of controlling network latency.

New algorithms are beginning to emerge to control queueing latency directly to address the bufferbloat problem [CoDel]. Along these lines, PIE also aims to keep the benefits of RED: including easy implementation and scalability to high speeds. Similar to RED, PIE randomly drops an incoming packet at the onset of the congestion. The congestion detection, however, is based on the queueing latency instead of the queue length like RED. Furthermore, PIE also uses the derivative (rate of change) of the queueing latency to help determine congestion levels and an appropriate response. The design parameters of PIE are chosen via control theory stability analysis. While these parameters can be fixed to work in various traffic conditions, they could be made self-tuning to optimize system performance.

Separately, it is assumed that any latency-based AQM scheme would be applied over a Fair Queueing (FQ) structure or one of its approximate designs, Flow Queueing or Class Based Queueing (CBQ). FQ is one of the most studied scheduling algorithms since it was first proposed in 1985 [RFC970]. CBQ has been a standard feature in most network devices today[CBQ]. Any AQM scheme that is built on top of FQ or CBQ could benefit from these advantages. Furthermore, these advantages such as per flow/class fairness are orthogonal to the AQM design whose primary goal is to control latency for a given queue. For flows that are classified into the same class and put into the same queue, one needs to ensure their latency is better controlled and their fairness is not worse than those under the standard DropTail or RED design. More details about the relationship between FQ and AQM can be found in IETF draft [FQ-Implement].

In October 2013, CableLabs' DOCSIS 3.1 specification [DOCSIS_3.1] mandated that cable modems implement a specific variant of the PIE design as the active queue management algorithm. In addition to cable specific improvements, the PIE design in DOCSIS 3.1 [DOCSIS-PIE] has improved the original design in several areas, including de-randomization of coin tosses and enhanced burst protection.

This draft describes the design of PIE and separates it into basic elements and optional components that may be implemented to enhance the performance of PIE.

2. Terminology

The key words "MUST", "MUST NOT", "REQUIRED", "SHALL", "SHALL NOT", "SHOULD", "SHOULD NOT", "RECOMMENDED", "MAY", and "OPTIONAL" in this document are to be interpreted as described in RFC 2119 [RFC2119].

3. Design Goals

A queue management framework is designed to improve the performance of interactive and latency-sensitive applications. It should follow the general guidelines set by the AQM working group document "Recommendations Regarding Active Queue Management" [RFC7567]. More specifically PIE design has the following basic criteria.

- * First, queueing latency, instead of queue length, is controlled. Queue sizes change with queue draining rates and various flows' round trip times. Latency bloat is the real issue that needs to be addressed as it impairs real time applications.

If latency can be controlled, bufferbloat is not an issue. In fact, once latency is under control it frees up buffers for sporadic bursts.

* Secondly, PIE aims to attain high link utilization. The goal of low latency shall be achieved without suffering link under-utilization or losing network efficiency. An early congestion signal could cause TCP to back off and avoid queue building up. On the other hand, however, TCP's rate reduction could result in link under-utilization. There is a delicate balance between achieving high link utilization and low latency.

* Furthermore, the scheme should be simple to implement and easily scalable in both hardware and software. PIE strives to maintain similar design simplicity to RED, which has been implemented in a wide variety of network devices.

* Finally, the scheme should ensure system stability for various network topologies and scale well across an arbitrary number of streams. Design parameters shall be set automatically. Users only need to set performance-related parameters such as target queue latency, not design parameters.

In the following, the design of PIE and its operation are described in detail.

4. The Basic PIE Scheme

As illustrated in Fig. 1, PIE is comprised of three simple basic components: a) random dropping at enqueueing; b) periodic drop probability update; c) latency calculation. When a packet arrives, a random decision is made regarding whether to drop the packet. The drop probability is updated periodically based on how far the current latency is away from the target and whether the queueing latency is currently trending up or down. The queueing latency can be obtained using direct measurements or using estimations calculated from the queue length and the dequeue rate.

The detailed definition of parameters can be found in the pseudo code section of this document (Section 11). Any state variables that PIE maintains are noted using "PIE->". For full description of the algorithm, one can refer to the full paper [HPSR-PIE].

Figure 1. The PIE Structure

4.1 Random Dropping

PIE randomly drops a packet upon its arrival to a queue according to a drop probability, `PIE->drop_prob_`, that is obtained from the drop-probability-calculation component. The random drop is triggered by a packet arrival before enqueueing into a queue.

* Upon a packet enqueue:

randomly drop the packet with a probability `PIE->drop_prob_`.

To ensure that PIE is work conserving, we bypass the random drop if the latency sample, `PIE->qdelay_old_`, is smaller than half of the target latency value (`QDELAY_REF`) when the drop probability is not too high, `PIE->drop_prob_ < 0.2`; or if the queue has less than a couple of packets.

* Upon a packet enqueue, PIE:

```
//Safeguard PIE to be work conserving
if ( (PIE->qdelay_old_ < QDELAY_REF/2 && PIE->drop_prob_ < 0.2)
    || (queue_.byte_length() <= 2 * MEAN_PKTSIZE) ) {
    return ENQUEUE;
}
else
    randomly drop the packet with a probability PIE->drop_prob_.
```

PIE optionally supports ECN and see Section 5.1.

4.2 Drop Probability Calculation

The PIE algorithm periodically updates the drop probability based on the latency samples: not only the current latency sample but also the trend where the latency is going, up or down. This is the classical Proportional Integral (PI) controller method which is known for eliminating steady state errors. This type of controller has been studied before for controlling the queue length [PI, QCN]. PIE adopts the Proportional Integral controller for controlling latency. The algorithm also auto-adjusts the control parameters based on how heavy the congestion is, which is reflected in the current drop probability. Note that the current drop probability is a direct measure of current congestion level, no need to measure the arrival rate and dequeue rate mismatches.

When a congestion period goes away, we might be left with a high drop probability with light packet arrivals. Hence, the PIE algorithm includes a mechanism by which the drop probability decay exponentially (rather than linearly) when the system is not congested. This would help the drop probability converge to 0 faster while the PI controller ensures that it would eventually reaches zero. The decay parameter of 2% gives us a time constant around $50 * T_UPDATE$.

Specifically, the PIE algorithm periodically adjust the drop probability every T_UPDATE interval:

* calculate drop probability `PIE->drop_prob_` and auto-tune it as:

```
p = alpha*(current_qdelay-QDELAY_REF) +
    beta*(current_qdelay-PIE->qdelay_old_);

if (PIE->drop_prob_ < 0.000001) {
    p /= 2048;
} else if (PIE->drop_prob_ < 0.00001) {
    p /= 512;
} else if (PIE->drop_prob_ < 0.0001) {
    p /= 128;
} else if (PIE->drop_prob_ < 0.001) {
    p /= 32;
} else if (PIE->drop_prob_ < 0.01) {
    p /= 8;
} else if (PIE->drop_prob_ < 0.1) {
    p /= 2;
```

```
    } else {
        p = p;
    }
    PIE->drop_prob_ += p;

* decay the drop probability exponentially:

    if (current_qdelay == 0 && PIE->qdelay_old_ == 0) {
        PIE->drop_prob_ = PIE->drop_prob_*0.98;    //1- 1/64
                                                    //is sufficient
    }

* bound the drop probability
    if (PIE->drop_prob_ < 0)
        PIE->drop_prob_ = 0.0
    if (PIE->drop_prob_ > 1)
        PIE->drop_prob_ = 1.0

* store current latency value:

    PIE->qdelay_old_ = current_qdelay.
```

The update interval, `T_UPDATE`, is defaulted to be 15ms. It MAY be reduced on high speed links in order to provide smoother response. The target latency value, `QDELAY_REF`, SHOULD be set to 15ms. Variables, `current_qdelay` and `PIE->qdelay_old_` represent the current and previous samples of the queueing latency, which are calculated by the "Latency Calculation" component (see Section 4.3). The variable `current_qdelay` is actually a temporary variable while `PIE->qdelay_old_` is a state variable that PIE keeps. The drop probability is a value between 0 and 1. However, implementations can certainly use integers.

The controller parameters, α and β (in the unit of hz) are designed using feedback loop analysis where TCP's behaviors are modeled using the results from well-studied prior art [TCP-Models]. Note that the above adjustment of 'p' effectively scales the α and β parameters based on current congestion level indicated by the drop probability.

The theoretical analysis of PIE can be found in [HPSR-PIE]. As a rule of thumb, to keep the same feedback loop dynamics, if we cut `T_UPDATE` in half, we should also cut α by half and increase β by $\alpha/4$. If the target latency is reduced, e.g. for data center use, the values of α and β should be increased by the same order of magnitude that the target latency is reduced. For example, if `QDELAY_REF` is reduced

changed from 15ms to 150us, a reduction of two orders of magnitude, then alpha and beta values should be increased to alpha*100 and beta*100.

4.3 Latency Calculation

The PIE algorithm uses latency to calculate drop probability.

* It estimates current queueing latency using Little's law:

```
current_qdelay = queue_.byte_length()/dequeue_rate;
```

Details can be found in Section 5.2.

* or it may use other techniques for calculating queueing latency, ex: timestamp packets at enqueue and use the same to calculate latency during dequeue.

4.4 Burst Tolerance

PIE does not penalize short-term packet bursts as suggested in RFC7567 [RFC7567]. PIE allows bursts of traffic that create finite-duration events in which current queueing latency exceeds the QDELAY_REF, without triggering packet drops. A parameter, MAX_BURST, is introduced that defines the burst duration that will be protected. By default, the parameter SHOULD be set to be 150ms. For simplicity, the PIE algorithm MAY effectively round MAX_BURST up to an integer multiple of T_UPDATE.

To implement the burst tolerance function, two basic components of PIE are involved: "random dropping" and "drop probability calculation". The PIE algorithm does the following:

* In "Random Dropping" block and upon a packet arrival , PIE checks:

```
Upon a packet enqueue:  
if PIE->burst_allowance_ > 0 enqueue packet;  
else randomly drop a packet with a probability PIE->drop_prob_.
```

```
if (PIE->drop_prob_ == 0 and current_qdelay < QDELAY_REF/2 and  
PIE->qdelay_old_ < QDELAY_REF/2)  
    PIE->burst_allowance_ = MAX_BURST;
```

* In "Drop Probability Calculation" block, PIE additionally calculates:

```
PIE->burst_allowance_ = max(0,PIE->burst_allowance_ -
```

```
T_UPDATE);
```

The burst allowance, noted by `PIE->burst_allowance_`, is initialized to `MAX_BURST`. As long as `PIE->burst_allowance_` is above zero, an incoming packet will be enqueued bypassing the random drop process. During each update instance, the value of `PIE->burst_allowance_` is decremented by the update period, `T_UPDATE` and is bottomed at 0. When the congestion goes away, defined here as `PIE->drop_prob_` equals 0 and both the current and previous samples of estimated latency are less than half of `QDELAY_REF`, `PIE->burst_allowance_` is reset to `MAX_BURST`.

5. Optional Design Elements of PIE

The above forms the basic elements of the PIE algorithm. There are several enhancements that are added to further augment the performance of the basic algorithm. For clarity purposes, they are included in this section.

5.1 ECN Support

PIE MAY support ECN by marking (rather than dropping) ECN capable packets [IETF-ECN]. As a safeguard, an additional threshold, `mark_ecnth`, is introduced. If the calculated drop probability exceeds `mark_ecnth`, PIE reverts to packet drop for ECN capable packets. The variable `mark_ecnth` SHOULD be set at 0.1(10%).

- * To support ECN, the "random drop with a probability `PIE->drop_prob_`" function in "Random Dropping" block are changed to the following:

- * Upon a packet enqueue:

```
if rand() < PIE->drop_prob_:
    if PIE->drop_prob_ < mark_ecnth && ecn_capable_packet == TRUE:
        mark packet;
    else:
        drop packet;
```

5.2 Dequeue Rate Estimation

Using the timestamps, a latency sample can only be obtained when a packet reaches at the head of a queue. When a quick response time is desired or a direct latency sample is not available, one may obtain latency through measuring the dequeue rate. The draining rate of a queue in the network often varies either because other queues are sharing the same link, or the link capacity fluctuates. Rate fluctuation is particularly common in wireless networks. One may measure directly at the dequeue operation. Short, non-persistent bursts of packets result in empty queues from time to time, this would make the measurement less accurate. PIE measures when a sufficient data in the buffer, i.e., when the queue length is over a certain threshold (DQ_THRESHOLD). PIE measures how long it takes to drain DQ_THRESHOLD of packets. More specifically, the rate estimation can be implemented as follows:

```
current_qdelay = queue_.byte_length() *
                PIE->avg_dq_time_/DQ_THRESHOLD;
```

* Upon a packet deque:

```
if PIE->in_measurement_ == FALSE and queue.byte_length() >=
DQ_THRESHOLD:
    PIE->in_measurement_ = TRUE;
    PIE->measurement_start_ = now;
    PIE->dq_count_ = 0;

if PIE->in_measurement_ == TRUE:
    PIE->dq_count_ = PIE->dq_count_ + deque_pkt_size;
    if PIE->dq_count_ >= DQ_THRESHOLD then
        weight = DQ_THRESHOLD/2^16
        PIE->avg_dq_time_ = (now-PIE->measurement_start_)*weight
                        + PIE->avg_dq_time_*(1-weight);
        PIE->dq_count_=0;
        PIE->measurement_start_ = now
    else
        PIE->in_measurement_ = FALSE;
```

The parameter, PIE->dq_count_, represents the number of bytes departed since the last measurement. Once PIE->dq_count_ is over DQ_THRESHOLD, a measurement sample is obtained. The threshold is recommended to be set to 16KB assuming a typical packet size of around 1KB or 1.5KB. This threshold would allow sufficient data to obtain an average draining rate but also fast enough (< 64KB) to reflect sudden changes in the draining rate. IF DQ_THRESHOLD is smaller than 64KB, a small weight is used to smooth out the dequeue time and obtain PIE->avg_dq_time_. The dequeue rate is simply DQ_THRESHOLD divided by PIE->avg_dq_time_. This threshold is not crucial for the system's stability. Please note that the update interval for calculating the drop probability is different from the rate measurement cycle. The drop probability calculation is done periodically

per section 4.2 and it is done even when the algorithm is not in a measurement cycle; in this case the previously latched value of `PIE->avg_dq_time_` is used.

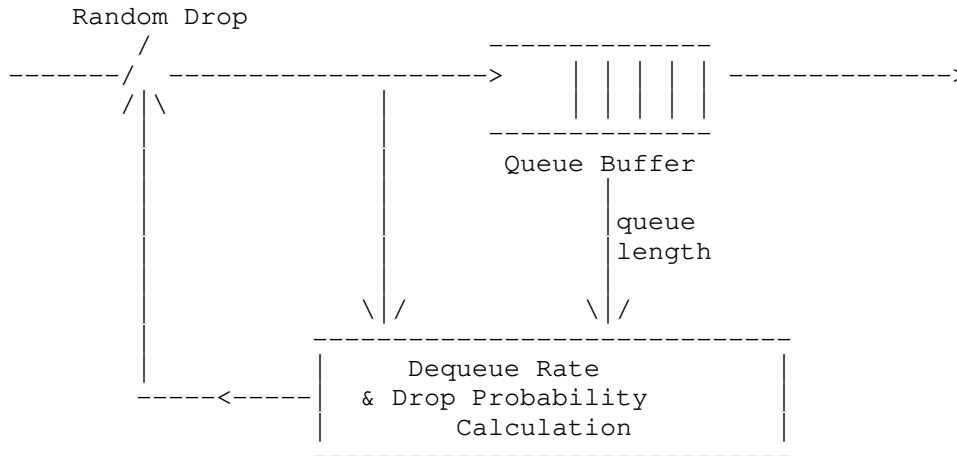

Figure 2. The Enqueue-based PIE Structure

In some platforms, enqueueing and dequeueing functions belong to different modules that are independent of each other. In such situations, a pure enqueue-based design can be designed. As shown in Figure 2, an enqueue-based design is depicted. The dequeue rate is deduced from the number of packets enqueued and the queue length. The design is based on the following key observation: over a certain time interval, the number of dequeued packets = the number of enqueued packets - the number of remaining packets in queue. In this design, everything can be triggered by a packet arrival including the background update process. The design complexity here is similar to the original design.

5.3 Setting PIE active and inactive

Traffic naturally fluctuates in a network. It would be preferable not to unnecessarily drop packets due to a spurious uptick in queueing latency. PIE has an optional feature of automatically becoming active/inactive. To implement this feature, PIE may choose to only become active (from inactive) when the buffer occupancy is over a certain threshold, which

may be set to 1/3 of the tail drop threshold. PIE becomes inactive when congestion is over, i.e. when the drop probability reaches 0, current and previous latency samples are all below half of QDELAY_REF.

Ideally, PIE should become active/inactive based on the latency. However, calculating latency when PIE is inactive would introduce unnecessary packet processing overhead. Weighing the trade-offs, it is decided to compare against tail drop threshold to keep things simple.

When PIE is optionally becomes active/inactive, the burst protection logic in Section 4.4 are modified as follows:

* "Random Dropping" block, PIE adds:

Upon packet arrival:

```

if PIE->active_ == FALSE && queue_length >= TAIL_DROP/3:
    PIE->active_ = TRUE;
    PIE->burst_allowance_ = MAX_BURST;

if PIE->burst_allowance_ > 0 enqueue packet;
else randomly drop a packet with a probability PIE->drop_prob_.

if (PIE->drop_prob_ == 0 and current_qdelay < QDELAY_REF/2 and
    PIE->qdelay_old_ < QDELAY_REF/2)
    PIE->active_ = FALSE;
    PIE->burst_allowance_ = MAX_BURST;

```

* "Drop Probability Calculation" block, PIE does the following:

```

if PIE->active_ == TRUE:
    PIE->burst_allowance_ = max(0,PIE->burst_allowance_ - T_UPDATE);

```

5.4 De-randomization

Although PIE adopts random dropping to achieve latency control, independent coin tosses could introduce outlier situations where packets are dropped too close to each other or too far from each other. This would cause real drop percentage to temporarily deviate from the intended value PIE->drop_prob_. In certain scenarios, such as small number of simultaneous TCP flows, these deviations can cause significant deviations in link utilization and queuing latency. PIE may use a de-randomization mechanism to avoid such situations. A parameter, called PIE->accu_prob_, is reset to 0 after a drop. Upon a packet arrival, PIE->accu_prob_ is incremented by the amount of drop probability, PIE->drop_prob_. If PIE->accu_prob_ is less than a low threshold, e.g. 0.85, the arriving packet is enqueued; on the other hand, if PIE->accu_prob_ is more than a high threshold, e.g. 8.5, and the queue is congested, the

arrival packet is forced to be dropped. A packet is only randomly dropped if `PIE->accu_prob_` falls in between the two thresholds. Since `PIE->accu_prob_` is reset to 0 after a drop, another drop will not happen until $0.85/PIE->drop_prob_$ packets later. This avoids packets being dropped too close to each other. In the other extreme case where $8.5/PIE->drop_prob_$ packets have been enqueued without incurring a drop, PIE would force a drop in order to prevent the drops from being spaced too far apart. Further analysis can be found in [DOCSIS-PIE].

5.5 Cap Drop Adjustment

In the case of one single TCP flow during slow start phase in the system, queue could quickly increase during slow start and demands high drop probability. In some environments such as Cable Modem Speed Test, one could not afford triggering timeout and lose throughput as throughput is shown to customers who are testing his/her connection speed. PIE could cap the maximum drop probability increase in each step.

* "Drop Probability Calculation" block, PIE adds:

```
if (PIE->drop_prob_ >= 0.1 && p > 0.02) {  
    p = 0.02;  
}
```

6. Implementation Cost

PIE can be applied to existing hardware or software solutions. There are three steps involved in PIE as discussed in Section 4. Their complexities are examined below.

Upon packet arrival, the algorithm simply drops a packet randomly based on the drop probability. This step is straightforward and requires no packet header examination and manipulation. If the implementation doesn't rely on packet timestamps for calculating latency, PIE does not require extra memory. Furthermore, the input side of a queue is typically under software control while the output side of a queue is hardware based. Hence, a drop at enqueueing can be readily retrofitted into existing or software implementations.

The drop probability calculation is done in the background and it occurs every `T_UPDATE` interval. Given modern high speed links, this period translates into once every tens, hundreds or even thousands of packets. Hence the calculation occurs at a much slower time scale than packet processing time, at least an order of magnitude slower. The calculation of drop probability involves multiplications using alpha and beta. Since PIE's control law is robust to minor changes in alpha and beta values,

an implementation MAY choose these values to the closest multiples of 2 or 1/2 (ex: $\alpha=1/8$, $\beta=1 + 1/4$) such that the multiplications can be done using simple adds and shifts. As no complicated functions are required, PIE can be easily implemented in both hardware and software. The state requirement is only one variables per queue: PIE->qdelay_old_. Hence the memory overhead is small.

If one chooses to implement the departure rate estimation, PIE uses a counter to keep track of the number of bytes departed for the current interval. This counter is incremented per packet departure. Every T_UPDATE, PIE calculates latency using the departure rate, which can be implemented using a multiplication. Note that many network devices keep track of an interface's departure rate. In this case, PIE might be able to reuse this information, simply skip the third step of the algorithm and hence incurs no extra cost. If a platform already leverages packet timestamps for other purposes, PIE can make use of these packet timestamps for latency calculation instead of estimating departure rate.

Flow queuing can also be combined with PIE to provide isolation between flows. In this case, it is preferable to have an independent value of drop probability per queue. This allows each flow to receive the most appropriate level of congestion signal, and ensures that sparse flows are protected from experiencing packet drops. However, running the entire PIE algorithm independently on each queue in order to calculate the drop probability may be overkill. Furthermore, in the case that departure rate estimation is used to predict queuing latency, it is not possible to calculate an accurate per-queue departure rate upon which to implement the PIE drop probability calculation. Instead, it has been proposed ([DOCSIS_AQM]) that a single implementation of the PIE drop probability calculation based on the overall latency estimate be used, followed by a per-queue scaling of drop-probability based on the ratio of queue-depth between the queue in question and the current largest queue. This scaling is reasonably simple, and has a couple of nice properties. One, if a packet is arriving to an empty queue, it is given immunity from packet drops altogether, regardless of the state of the other queues. Two, in the situation where only a single queue is in use, the algorithm behaves exactly like the single-queue PIE algorithm.

In summary, PIE is simple enough to be implemented in both software and hardware.

7. Scope of Experimentation

The design of the PIE algorithm is presented in this document. It

effectively controls the average queuing latency to a target value. The following areas can be further studied and experimented:

- * Autotuning of target latency without losing utilization;
- * Autotuning for average RTT of traffic;
- * The proper threshold to transition smoothly between ECN marking and dropping;
- * The enhancements in Section 5 can be experimented to see if they would bring more value in the real world. If so, they will be incorporated into the basic PIE algorithm;
- * The PIE design is separated into data path and control path, and the control path can be implemented in software. Field tests of other control laws can be experimented to further improve PIE's performance.

Although all network nodes cannot be changed altogether to adopt latency-based AQM schemes such as PIE, a gradual adoption would eventually lead to end-to-end low latency service for all applications.

8. Incremental Deployment

From testbed experiments and large scale simulations of PIE so far, PIE has been shown to be effective across diverse range of network scenarios. There is no indication that PIE would be harmful to deploy.

The PIE scheme can be independently deployed and managed without a need for interoperability between different network devices. In addition, any individual buffer queue can be incrementally upgraded to PIE as it can co-exist with existing AQM schemes such as WRED.

PIE is intended to be self-configuring. Users should not need to configure any design parameters. Upon installation, the two user-configurable parameters: QDELAY_REF and MAX_BURST, will be defaulted to 15ms and 150ms for non datacenter network devices and to 15us and 150us for datacenter switches, respectively.

Since the data path of the algorithm needs only a simple coin toss and the control path calculation happens in a much slower time scale, We don't foresee any scaling issues associated with the algorithm as the link speed scales up.

9. Security Considerations

This document describes an active queue management algorithm based on implementations in different products. This algorithm introduces no specific security exposures.

10. IANA Considerations

There are no actions for IANA.

12. The Basic PIE pseudo Code

Configurable Parameters:

- QDELAY_REF. AQM Latency Target (default: 15ms)
- MAX_BURST. AQM Max Burst Allowance (default: 150ms)

Internal Parameters:

- Weights in the drop probability calculation (1/s):
alpha (default: 1/8), beta (default: 1 + 1/4)
- T_UPDATE: a period to calculate drop probability (default: 15ms)

Table which stores status variables (ending with "_"):

- burst_allowance_: current burst allowance
- drop_prob_: The current packet drop probability. reset to 0
- qdelay_old_: The previous queue delay. reset to 0

Public/system functions:

- queue_. Holds the pending packets.
- drop(packet). Drops/discards a packet
- now(). Returns the current time
- random(). Returns a uniform r.v. in the range 0 ~ 1
- queue_.byte_length(). Returns current queue_ length in bytes
- queue_.enqueue(packet). Adds packet to tail of queue_
- queue_.dequeue(). Returns the packet from the head of queue_
- packet.size(). Returns size of packet
- packet.timestamp_delay(). Returns timestamped packet latency

=====

```
//called on each packet arrival
enqueue(Packet packet) {
    if (PIE->drop_prob_ == 0 && current_qdelay < QDELAY_REF/2
        && PIE->qdelay_old_ < QDELAY_REF/2) {
        PIE->burst_allowance_ = MAX_BURST;
    }
    if (PIE->burst_allowance_ == 0 && drop_early() == DROP) {
        drop(packet);
    } else {
        queue_.enqueue(packet);
    }
}
```

=====

```
drop_early() {

    //Safeguard PIE to be work conserving
    if ( (PIE->qdelay_old_ < QDELAY_REF/2 && PIE->drop_prob_ < 0.2)
        || (queue_.byte_length() <= 2 * MEAN_PKT_SIZE) ) {
        return ENQUE;
    }

    double u = random();
    if (u < PIE->drop_prob_) {
        return DROP;
    } else {
```

```
        return ENQUE;
    }
}

=====
//we choose the timestamp option of obtaining latency for clarity
//rate estimation method can be found in the extended PIE pseudo code

deque(Packet packet) {

    current_qdelay = packet.timestamp_delay();

}

    }
}

```

13. Pseudo code for PIE with optional enhancement

Configurable Parameters:

- QDELAY_REF. AQM Latency Target (default: 15ms)
- MAX_BURST. AQM Max Burst Allowance (default: 150ms)
- MAX_ECINTH. AQM Max ECN Marking Threshold (default: 10%)

Internal Parameters:

- Weights in the drop probability calculation (1/s):
alpha (default: 1/8), beta(default: 1+1/4)
- DQ_THRESHOLD: (in bytes, default: 2¹⁴ (in a power of 2))
- T_UPDATE: a period to calculate drop probability (default:15ms)
- TAIL_DROP: each queue has a tail drop threshold, pass it to PIE

Table which stores status variables (ending with "_"):

- active_: INACTIVE/ACTIVE
- burst_allowance_: current burst allowance
- drop_prob_: The current packet drop probability. reset to 0
- accu_prob_: Accumulated drop probability. reset to 0
- qdelay_old_: The previous queue delay estimate. reset to 0
- last_timestamp_: Timestamp of previous status update
- dq_count_, measurement_start_, in_measurement_,
avg_dq_time_. variables for measuring average dequeue rate.

Public/system functions:

- queue_. Holds the pending packets.
- drop(packet). Drops/discards a packet
- mark(packet). Marks ECN for a packet
- now(). Returns the current time

- random(). Returns a uniform r.v. in the range 0 ~ 1
- queue_.byte_length(). Returns current queue_ length in bytes
- queue_.enqueue(packet). Adds packet to tail of queue_
- queue_.deque(). Returns the packet from the head of queue_
- packet.size(). Returns size of packet
- packet.ecn(). Returns whether packet is ECN capable or not

```

=====
//called on each packet arrival
enqueue(Packet packet) {

Global Synchronization Protection for Packet Queues
draft-lauten-aqm-gsp-03.txt

Abstract

The congestion avoidance processes of transmission capacity sharing TCP flows tend to be synchronized among each other, so that the rate variations of the individual flows do not compensate. In contrary, they accumulate into large variations of the whole aggregate. The effect is known as global synchronization. Large queuing buffer demand and large latency and jitter are the consequences. Global Synchronization Protection (GSP) is an extension of regular tail drop packet queuing schemes that prevents global synchronization. For large traffic aggregates the de-correlation between the individual flow variations reduces buffer demand and packet sojourn time by an order of magnitude and more. Even though quite simple, the solution has a theoretical background and is not heuristic. It has been tested with a Linux kernel implementation and shows equivalent performance as other relevant AQM schemes.

Status of this Memo

This Internet-Draft is submitted in full conformance with the provisions of BCP 78 and BCP 79.

Internet-Drafts are working documents of the Internet Engineering Task Force (IETF), its areas, and its working groups. Note that other groups may also distribute working documents as Internet-Drafts.

Internet-Drafts are draft documents valid for a maximum of six months and may be updated, replaced, or obsoleted by other documents at any time. It is inappropriate to use Internet-Drafts as reference material or to cite them other than as "work in progress."

1. Introduction

The congestion window (CWND) of a particular TCP connection, in combination with the round trip time (RTT), limits the transmission rate of the flow, which enables adaptation of the sending rate to the actual network conditions, [1]. TCP uses a rather coarse congestion control feedback by halving the congestion window in response to

packet loss. To fill a bottleneck link by 100% anyway, a packet buffer in front of the link is required. For a single TCP flow a buffer in the range of bottleneck capacity multiplied by the round trip time is required (bandwidth-delay product rule, BDP), [2]. For aggregated traffic of many flows the picture is not so clear. Conservative estimations tend towards BDP of the whole aggregate, i.e. link capacity * RTT. At the other hand, rate reductions due to CWND halving are still only in the range of a particular flow rate. With the assumption of N sharing flows, this yields ideally a buffer size of only (link capacity/N)*RTT. Unfortunately this value cannot be reached in practice. It would require a uniform distribution of rate reductions by the different flows over time. In opposite, rate reductions of bottleneck sharing flows tend to synchronize among each other, which is called global synchronization. In worst case, with all flows synchronized, the buffer demand is back at BDP of the whole traffic, thus confirming the conservative estimation.

There are cases where global synchronization does not occur, in particular large number of flows ($N > 500$), large spread of RTT between the different flows, and high frequency of flow renewals. In these cases the buffer size can be reduced to BDP/\sqrt{N} , which lies between the conservative and overly optimistic estimations above, [3]. Nevertheless there are still doubts, whether the absence of global synchronization is a general reliable design assumption for high capacity links, [4].

Most Active Queue Management (AQM) algorithms are aiming at better control of the queue size (RED [5]) or the queue delay (CoDel [6], PIE [7]), which implies control over global synchronization. Global Synchronization Protection (GSP [10]) goes the other way round. It suppresses the root cause of global synchronization and de-correlates the CWND variations of the competing flows, but it does not try to impact the behavior of a particular flow. This way it moves the buffer size demand down from conservative BDP of the whole link into the direction towards the ideal BDP of only one of the competing flows.

Experiments on GSP performance, as reported in [10], show that the stabilizing effect of GSP is equivalent to that of the other AQMs. It is a simple extension to plain tail drop queues. The basic algorithm is memoryless and does not need artificial randomization. Particularly for small numbers of flows it performs better than randomized AQMs like e.g. RED or PIE. Without any special precautions GSP is robust to bursts and never drops at low or empty queues. Automatic parameter adaptation, if needed at all, is external to the basic control loop, which makes it less time critical and less

sensitive to traffic conditions than other AQMs with integrated control and adaptation loops.

2. Conventions used in this document

In this document, the term "packet drop" is used for congestion notification, silently assuming that congestion marking for ECN could be equally applied.

In this document, the term "queue size" is preferably applied in number of bytes, however, the algorithm could be also applied to the number of packets, or even to the queuing delay (milliseconds).

3. Root cause of global synchronization

Global synchronization occurs in cases where a number of greedy TCP flows with comparably uniform RTT cross a tail drop queue in front of a shared transmission link. Greedy TCP means, the flow is probing the available capacity on this particular link and is not limited elsewhere (up- or downstream). Tail drop means, a newly arriving packet is placed at the end of the queue if buffer space permits. Otherwise it is dropped. The queue is drained from head of the queue at the speed of the link as long as packets are available.

In congestion avoidance state, all senders gradually increase their sending rate, which is, after a while, exceeding the link capacity so that the queue in front of the link is filling up. At some point in time, a first packet is dropped due to lack of buffer space. Ideally, the TCP flow, where the dropped packet belongs to, reduces its sending rate, the queue relaxes, its size goes down, and subsequently arriving packets again can be placed in the buffer. Senders continue to increase their sending rates until the next drop, and so on.

Unfortunately not one, but several packets get dropped in such incident for following reason: The rate reduction due to the first dropped packet needs at least one RTT to take effect at the queue entry. During that RTT interval all senders continue to gradually increase their sending rates, whereas the queue is still full. Further packets need to be dropped. It can be shown analytically that for N flows with NewReno and delayed ACK the number of drops is in the range of $N/2$. Experiments confirm this and show an even higher number with CUBIC. The outcome is that even though the rate reduction by one flow would suffice, not one, but as much as half of the flows are triggered within one RTT to reduce their sending rates - we have global synchronization. A more detailed analytical and experimental investigation of the effect can be found in [8].

4. Protecting queues of global synchronization

4.1. Basic algorithm

The basic algorithm works as follows: Set a threshold on queue size below the actual buffer size. If a new packet arrives and the queue size is above the threshold, then immediately drop that packet. After that, ignore any further threshold violation for a timeout interval of 1 - 3 RTT. After expiry of the timeout proceed as above.

Algorithm:

```
initialization:
  interval = e.g. 2 * RTT
  threshold = e.g. 1/2 * buffer size
  timeout_expiry = now(), with now() returning the current time

at any packet arrival do:
  if queue_size > threshold && now() > timeout_expiry:
    drop this packet
    timeout_expiry = now() + interval
  else
    enqueue this packet
```

The first dropped packet is triggering the rate reduction by one of the end points. During the timeout the queue is growing further beyond the threshold until the rate reduction takes effect at queue entry. Afterwards the queue size should have dropped below the threshold, so that at timeout expiry the threshold is typically not violated anymore. No explicit action occurs at timeout expiry, which makes the parameter rather insensitive to the actual traffic characteristics. Even if the timeout interval is too short, the algorithm still reduces global synchronization.

4.2. Interval adaptation at large flow numbers

The basic algorithm works well for moderate numbers of flows N , i.e. in a range of $1 < N < 20$. More precisely, at flow numbers N smaller than the average CWND of one of the sharing flows. At larger numbers the total rate increase during the timeout interval is larger than the subsequent rate reduction by one of the flows. As consequence, after timeout expiry the threshold is still violated, the queue is growing further and further, and, eventually, reaches the buffer limit and enters tail drop operation. The performance is still better

than plain tail drop and one could rely on the observation that at large flow numbers global synchronization disappears, anyway.

Alternatively the initial timeout interval can be reduced, depending on the actual traffic, in a way, where not just once, but twice, or even more times per RTT the timeout expires. The adaptation criterion is the proportion of time above and below threshold. In regular operation according to the basic algorithm, the queue is most of the time below the threshold. If, however, the queue is more frequently above than below threshold, the interval should be reduced until equilibrium is reached. In this condition the queue is oscillating around the threshold, periodically dropping during times above the threshold, quite similar like PED [9].

Algorithm:

initialization:

```
tau = a preset parameter controlling the adaptation speed;
      e.g. 500 milliseconds or 5 * initial_interval
initial_interval - the preset timeout interval as in the basic
                  algorithm
cumTime = 0; the cumulative time above/below threshold
state = CLEAR; the recent overflow state of the queue
```

at any packet arrival do:

```
if the packet would overflow the buffer (hard tail drop):
    state = OVERFLOW
if state == OVERFLOW && queue is empty:
    state = DRAIN
if state == DRAIN && queue_size > threshold:
    state = CLEAR
```

update the cumulative time cumTime:

```
account by twice the duration for queue episodes
that are entirely ABOVE the threshold
if status == CLEAR:
    account by negated duration for queue episodes
that are entirely BELOW the threshold
```

clamp the cumulative time:

```
cumTime = max(cumTime, 0)
cumTime = min(cumTime, some sanity limit
              of several minutes)
```

```
calculate timeout interval (to be used at next drop decision):
    interval = initial_interval/(1+cumTime/tau)
```

The adaptation heuristics works as follows: The basic GSP algorithm executes single drops per threshold violation as long as the cumulative time (cumTime) is clamped at zero. As soon as the cumulative time gets positive, the adaptation algorithm implements an integral controller for the drop rate that the basic GSP algorithm executes during times of threshold violation. The transition between both operating conditions is smooth. The adaptation speed is controlled by the parameter tau.

Plain adaptation by cumulative times above / below threshold might latch up in circumstances where abrupt traffic changes cause massive buffer overflows. To avoid this, after a hard buffer overflow the accounting for times below threshold is suspended until the queue performed a full cycle of down to empty and back above threshold.

4.3. Interval adaptation at small RTT

The RTT is not known exactly but there should be at least a rough idea on the range of RTT for setting up the timeout interval. If this estimation is much too large, a similar situation occurs like in the large flow numbers case. The total rate increase during the timeout interval (which turns out to be multiple RTTs) is larger than the subsequent rate reduction by one flow. The adaptation rule is the same as for large flow numbers, section 4.2.

4.4. Sanity checks and special cases

An additional rule can be introduced that prevents large packet bursts from immediately triggering the drop: Restart the timeout not only after a packet drop but also whenever a packet is arriving at an empty queue.

```
at any packet arrival do:
    if queue is empty:
        timeout_expiry = now() + interval
```

5. Delay based operation

5.1. Queue delay vs. queue size

Recent new AQM proposals ([6], [7]) are focusing on queue delay rather than on queue size in bytes. One reason for this move is that ideally the steady state queue oscillation depends only on the RTT and on the number of sharing TCP flows - if measured in delay. If measured in bytes, however, the queue oscillation additionally depends on the link capacity. The oscillation span sets the minimum queue size for 100% link utilization. (This is where the bandwidth delay product rule comes from.) A larger queue creates only unnecessary delay (standing queue).

Obviously it is preferable to stabilize the delay instead of the size. It eliminates the interface rate from the parameter list, which is particularly welcome in circumstances with unknown or variable drain rate. Such situations are typical for low priority queues in front of a priority scheduler and generally in wireless scenarios.

5.2. Delay based GSP

In section 4. we silently assumed queue size in bytes. However, the algorithm can be equally applied to the queue delay (packet sojourn time). In this case the threshold has to be in milliseconds, whereas the empty queue condition remains the same as before.

While the queue size in bytes or packets is typically maintained by ordinary queue implementations, obtaining the queue delay requires additional effort. Two solutions are available and both are applicable to GSP: Time stamping of packets like in CoDel [6] or estimating the drain rate for a translation of size into delay like in PIE [7].

Algorithm (time stamping):

```
at any arrival of a packet p do:
    p.time = now()
```

```
at any departure of a packet p do:
    queue_delay = now() - p.time
```

The basic algorithm of section 4.1. rephrased to delay based operation:

```
at any packet arrival do:
  if queue_delay > threshold && now() > timeout_expiry:
    drop this packet
    timeout_expiry = now() + interval
  else
    enqueue this packet
```

Please note that `queue_delay` is a per queue variable, not per packet, i.e. the drop decision at enqueueing (tail drop) depends on the delay that another, most recently dequeued packet experienced. This approach is a forecast of the expected delay and it is justified by the inherent inercance of the queue itself.

6. Security Considerations

Global synchronization is a particular problem of many elastic flows sharing a bottleneck. GSP is there to prevent this. But it does not protect of unresponsive flows. If the congestion notification according to section 4.1. randomly hits an unresponsive flow then the expected rate reduction within the timeout interval might simply not happen, which postpones the notification by one timeout interval. The interval adaptation of section 4.2. automatically ensures that the timeout interval is reduced accordingly, depending on the average fraction of unresponsive traffic. In extreme cases, when the unresponsive traffic alone is exceeding the link capacity, GSP behaves like plain tail drop.

7. IANA Considerations

There are no actions for IANA.
