BIER Use Case in Data Centers
draft-wang-bier-vxlan-use-case-01

Abstract

Bit Index Explicit Replication (BIER) is an architecture that provides optimal multicast forwarding through a "BIER domain" without requiring intermediate routers to maintain any multicast related per-flow state. BIER also does not require any explicit tree-building protocol for its operation. A multicast data packet enters a BIER domain at a "Bit-Forwarding Ingress Router" (BFIR), and leaves the BIER domain at one or more "Bit-Forwarding Egress Routers" (BFERs). The BFIR router adds a BIER header to the packet. The BIER header contains a bit-string in which each bit represents exactly one BFER to forward the packet to. The set of BFERs to which the multicast packet needs to be forwarded is expressed by setting the bits that correspond to those routers in the BIER header.

This document tries to describe the drawbacks of how BUM services are deployed in current data centers, and proposes how to take full advantage of BIER to implement BUM services in data centers.

1. Introduction

This document is motivated by [I-D.ietf-bier-use-cases].

In current data center virtualization, virtual eXtensible Local Area Network (VXLAN) [RFC7348] is a kind of network virtualization overlay technology which is overlaid between NVEs and is intended for multi-tenancy data center networks, whose reference architecture is illustrated as per Figure 1.

```
       +--------+                                             +--------+

```

Figure 1: NVO3 Architecture

And there are two kinds of most common methods about how to forward BUM packets in this virtualization overlay network. One is using PIM as underlay multicast routing protocol to build explicit multicast distribution tree, such as PIM-SM[RFC4601] or PIM-BIDIR [RFC5015]multicast routing protocol. Then, when BUM packets arrive at NVE, it requires NVE to have a mapping between the VXLAN Network Identifier and the IP multicast group. According to the mapping, NVE can encapsulate BUM packets in a multicast packet which group address is the mapping IP multicast group address and steer them through explicit multicast distribution tree to the destination NVEs. This method has two serious drawbacks. It need the underlay network supports complicated multicast routing protocol and maintains multicast related per-flow state in every transit nodes. What is more, how to configure the ratio of the mapping between VNI and IP multicast group is also an issue. If the ratio is 1:1, there should be 16M multicast groups in the underlay network at maximum to map to the 16M VNIs, which is really a significant challenge for the data center devices. If the ratio is n:1, it would result in inefficiency bandwidth utilization which is not optimal in data center networks.

The other method is using ingress replication to require each NVE to create a mapping between the VXLAN Network Identifier and the remote addresses of NVEs which belong to the same virtual network. When NVE receives BUM traffic from the attached tenant, NVE can encapsulate these BUM packets in unicast packets and replicate them and tunnel them to different remote NVEs respectively. Although this method can eliminate the burden of running multicast protocol in the underlay network, it has a significant disadvantage: large waste of bandwidth, especially in big-sized data center where there are many receivers.

Bit Index Explicit Replication (BIER) [I-D.ietf-bier-architecture] is an architecture that provides optimal multicast forwarding through a "BIER domain" without requiring intermediate routers to maintain any multicast related per-flow state. BIER also does not require any explicit tree-building protocol for its operation. A multicast data packet enters a BIER domain at a "Bit-Forwarding Ingress Router" (BFIR), and leaves the BIER domain at one or more "Bit-Forwarding Egress Routers" (BFERs). The BFIR router adds a BIER header to the packet. The BIER header contains a bit-string in which each bit represents exactly one BFER to forward the packet to. The set of BFERs to which the multicast packet needs to be forwarded is expressed by setting the bits that correspond to those routers in the BIER header. Specifically, for BIER-TE, the BIER header may also contain a bit-string in which each bit indicates the link the flow passes through.

The following sections try to propose how to take full advantage of overlay multicast protocol to carry virtual network information, and create a mapping between the virtual network information and the bit-string to implement BUM services in data centers.

2. Convention and Terminology

The key words "MUST", "MUST NOT", "REQUIRED", "SHALL", "SHALL NOT", "SHOULD", "SHOULD NOT", "RECOMMENDED", "MAY", and "OPTIONAL" in this document are to be interpreted as described in [RFC2119].

The terms about BIER are defined in [I-D.ietf-bier-architecture].

The terms about NVO3 are defined in [RFC7365].

Here tries to list the most common terminology mentioned in this draft.

BIER: Bit Index Explicit Replication(Bit Index Explicit Replication (The overall architecture of forwarding multicast using a Bit Position).

NVE: Network Virtualization Edge, which is the entity that implements the overlay functionality. An NVE resides at the boundary between a Tenant System and the overlay network.

VXLAN: Virtual eXtensible Local Area Network

VNI: VXLAN Network Identifier

Virtal Network Context Identifier: Field in an overlay encapsulation header that identifies the specific VN the packet belongs to.

3. BIER in data centers

This section tries to describe how to use BIER as an optimal scheme to forward the broadcast, unknown and multicast (BUM) packets when they arrive at the ingress NVE in data centers.

The principle of using BIER to forward BUM traffic is that: firstly, it requires each ingress NVE to have a mapping between the Virtual Network Context Identifier and the bit-string in which each bit represents exactly one egress NVE to forward the packet to. And then, when receiving the BUM traffic, the BFIR/Ingree NVE maps the receiving BUM traffic to the mapping bit-string, encapsulates the BIER header, and forwards the encapsulated BUM traffic into the BIER domain to the other BFERs/Egress NVEs indicated by the bit-string.

Furthermore, as for how each ingress NVE knows the other egress NVEs that belong to the same virtual network and creates the mapping is the main issue discussed below. Basically, BIER Multicast Listener Discovery is an overlay solution to support ingress routers to keep per-egress-router state to construct the BIER bit-string associated with IP multicast packets entering the BIER domain. The following section tries to extend BIER MLD to carry virtual network information(such as Virtual Network Context identifier), and advertise them between NVEs. When each NVE receive these information, they create the mapping between the virtual network information and the bit-string representing the other NVEs belonged to the same virtual network.

4. BIER MLD extension for Virtual Network information

Figure 2 draws the MLD report message format. In order to support Virtual Network information advertisement, one bit of the reserved field can be used to indicate that there is Virtual Network information in the message.

Figure 3: MLD Virtual Network information TLV

Type:

indicates Virtual Network information TLV. Value 1 indicates Virtual Network information advertisement. Value 2 indicates Virtual Network information withdraw.

Length: 1 cotet.

Encap Type:

indicates the encapsulation type the virtual netowrk using, such as VxLAN,NVGRE,Geneve and so on.

Virtual Network Context Idenfifier:

indicates the identifier of the virtual network. Different encapsulation type has different meaning for this field. In VxLAN encasulation type, this field indicates VxLAN Network Identifier. In NVGRE encapsulation type, this field indicates Virtual Subnet ID(VSID).In Geneve encapsulation type, this field indicates Virtual Network Identifier.

Each NVE acquires the Virtual Network information, and advertises this Virtual Network information to other NVEs through the MLD messages. If the NVE attaches to several virtual networks, it will carry several Virtual Network Context Identifiers in the Virtual Network advertisement message. if the NVE supports several encapsulation types, it will carry the Virtual Network Context Identifiers belonging to one encapsulation type in one Virtual Network information TLV. if one attached virtual network is migrated, the NVE will withdraw the Virtual Network information.

When ingress NVE receives the Virtual Network information advertisement message, it builds a mapping between the receiving Virtual Network Context Identifier in this message and the bit-string in which each bit represents one egress NVE who sends the same Virtual Network information. Subsequently, once this ingress NVE receives some other MLD advertisements which include the same Virtual Network information from some other NVEs , it updates the bit-string in the mapping and adds the corresponding sending NVE to the updated bit-string. Once the ingress NVE removes one virtual network, it will delete the mapping corresponding to this virtual network as well as send withdraw message to other NVEs.

After finishing the above interaction of MLD messages, each ingress NVE knows where the other egress NVEs are in the same virtual network. When receiving BUM traffic from the attached virtual network, each ingress NVE knows exactly how to encapsulate this traffic and where to forward them to.

This can be used in both IPv4 network and IPv6 network. In IPv4, IGMP protocol does the similar extension for carrying Virtual Network information TLV in Version 2 membership report message.

5. Security Considerations

It will be considered in a future revision.

6. IANA Considerations

There need one new Type for Virtual Network information TLV in MLD protocol and one in IGMP protocol.
