Message Authentication Codes for the Network Time Protocol  
draft-aanchal4-ntp-mac-02

Abstract

The Network Time Protocol (NTP) RFC 5905 [RFC5905] uses a message authentication code (MAC) to cryptographically authenticate its UDP packets. Currently, NTP packets are authenticated by appending a 128-bit key to the NTP data, and hashing the result with MD5 to obtain a 128-bit tag. However, as discussed in [BCK] and [RFC6151], this is not a secure MAC. As such, this draft considers different secure MAC algorithms for use with NTP, evaluates their performance, and recommends the use of CMAC-AES [RFC4493]. We also suggest deprecating the use of MD5 as defined in [RFC5905] for authenticating NTP packets.

Status of This Memo

This Internet-Draft is submitted in full conformance with the provisions of BCP 78 and BCP 79.

Internet-Drafts are working documents of the Internet Engineering Task Force (IETF). Note that other groups may also distribute working documents as Internet-Drafts. The list of current Internet-Drafts is at <http://datatracker.ietf.org/drafts/current/>.

Internet-Drafts are draft documents valid for a maximum of six months and may be updated, replaced, or obsoleted by other documents at any time. It is inappropriate to use Internet-Drafts as reference material or to cite them other than as "work in progress."

This Internet-Draft will expire on April 28, 2017.

1. Introduction

NTP uses a message authentication code (MAC) to authenticate its packets. Currently, NTP packets are authenticated by appending a 128-bit key to the NTP data, and hashing the result with MD5 to obtain a 128-bit tag. However, as discussed in [BCK] and [RFC6151], this not a secure MAC. As such, this draft considers different secure MAC algorithms for use with NTP, evaluates their performance, and recommends the use of CMAC-AES [RFC4493]. We also suggest deprecating the use of MD5, as defined in [RFC5905], for authenticating NTP packets.

1.1. Requirements Language

The key words "MUST", "MUST NOT", "REQUIRED", "SHALL", "SHALL NOT", "SHOULD", "SHOULD NOT", "RECOMMENDED", "MAY", and "OPTIONAL" in this document are to be interpreted as described in RFC 2119 [RFC2119].

## 2. MAC Algorithms

We consider five diverse MAC algorithms, which encompass hash-based HMAC-MD5 and HMAC-SHA224 [RFC2104], block cipher-based CMAC-AES [RFC4493], and universal hashing-based Galois MAC (GMAC) [RFC4543] and Poly1305(ChaCha20) as in section 2.6 of [RFC7539]. For completeness we also benchmark the legacy MD5(key||message) from [RFC5905].

Algorithm	Input Key Length (Bytes)	Output Tag Length (Bytes)
legacy MD5	16	16
HMAC-MD5	16	16
HMAC-SHA224	16	16
CMAC (AES)	16	16
GMAC (AES)	16	16
Poly1305 (ChaCha20)	32	16

The choice of algorithms evaluated here is motivated, in part, by standardization and availability of their open source implementations. All algorithms we consider, other than the plain MD5, are standardized. Four out of five algorithms are at least available in the OpenSSL library, while Poly1305(ChaCha20) is implemented in LibreSSL (a fork of OpenSSL) and also in BoringSSL (Google's implementation of OpenSSL).

The output tag length for HMAC-SHA224 is 28 bytes, but we truncate it to 16 bytes as in section 4 of [RFC7630] to fit into the NTP packet. As noted in section 6 of [RFC2104] it is safe to truncate the output of MACs as long as the truncated length is greater than 80-bits and not less than half the length of the hash output.

## 3. Requirements

### 3.1. Performance Requirements

In order to accurately compute the time, NTP ideally requires MAC algorithms to have a constant computational latency. However, this is generally not possible, since latency depends on the CPU load, temperature, and other uncontrollable factors. Instead, a MAC algorithm that requires fewer clock cycles for computation is preferred over one that requires more clock cycles, as this directly translates to a reduction in jitter (i.e., the variance of the latency for computing the MAC).

Throughput is another important consideration. NTP servers may have to deal with thousands of client requests per second. A study [NIST] on the usage analysis of NIST's NTP stratum 1 servers shows that these servers cater to 28,000 requests/second on an average, per server.

Most of the Internet is served by stratum 2 and stratum 3 servers, some of which are a part of voluntary NTP pool. These machines may be running old hardware. Generally, while benchmarking MAC algorithms, several optimization techniques on custom specialized hardware are used to get the best results. However, for the reason stated above we choose to benchmark performance on a range of software and hardware platforms with and without optimizations.

### 3.2. Security Requirements

There are several more constraints specific to NTP that need to be taken into account.

1. NTP servers are stateless, i.e. they do not keep per client state.
2. Per [RFC5905], NTP uses a pre-shared symmetric key. This makes key management difficult because there is no in-band mechanism for distributing keys. As such, to simplify key management, some deployments use the same pre-shared key at many servers (typically at the same stratum). In other words, the same key is used for several client/server associations.
3. [RFC5905] also has no in-band mechanism to refresh keys.

### 4. Performance Results

The NTP header is 48 bytes long. We therefore consider the latency and throughput for several secure MAC algorithms when computed over 48-byte messages.

We customize the in-built speed utility of OpenSSL-1.0.2g (03 May 2016) version to compute the latency and throughput for each MAC as shown in the tables below. OpenSSL, however, does not implement stream-cipher ChaCha20-based Poly1305 MAC algorithm. To speed test this MAC, we use LibreSSL 2.3.1, a fork of OpenSSL implementation. OpenSSL and LibreSSL are the most widely used cryptographic libraries and are used by the current NTP implementations.

Since the introduction of New Instruction (NI) set for hardware support in Intel chips, certain MACs like CMAC and GMAC have performance advantage on such machines. Based on this, we perform

two different benchmarks: one with AES-NI enabled and the other with it disabled. Benchmarks were taken on an x86\_64, Intel(R) Xeon(R) CPU E5-2676 v3 @ 2.40GHz with one core CPU.

This table shows throughput in terms of number of 48-byte NTP payload processed per second.

Algorithm	with AES-NI	without AES-NI
legacy MD5	3118K	3165K
HMAC-MD5	2742K	2749K
HMAC-SHA224	1265K	1267K
CMAC (AES)	7567K	4388K
GMAC (AES)	16612K	4627K
Poly1305 (ChaCha20)	2598K	2398K

This table shows latency in terms of number of CPU cycles per byte (cpb) when processing a 48-byte NTP payload.

Algorithm	with AES-NI	without AES-NI
legacy MD5	16.0	15.7
HMAC-MD5	18.2	18.1
HMAC-SHA224	39.4	39.0
CMAC (AES)	6.6	11.3
GMAC (AES)	3.0	10.8
Poly1305 (ChaCha20)	14.4	15.0

## 5. Other Hardware Platforms

We also perform tests on the following ARM CPU cores and PowerPC(PPC)core with OpenSSL 1.0.2h released May 2016. These cores are most commonly used in consumer products and Industrial Control Systems (ICS) components. We select these cores to cover the ARM architecture versions 5/6 to 8. The results vary depending on the availability of CPU specific optimizations. For example the used Cortex-A9 and Cortex-A53 CPU have a NEON unit and OpenSSL can utilize it to accelerate AES.

1. Freescale/Apple PPC74xx 1.5GHz
2. NXP i.MX6 1GHz (dual core) ARM Cortex-A9
3. Broadcom BCM2837 1.2GHz (quad core) ARM Cortex-A53

## 4. Marvell 88F6281 1.2GHz 88FR131 (ARMv5te compliant)

The table below shows throughput in terms of number of 48-byte NTP payload processed per second.

Algorithm	PPC74xx	ARM Cortex-A9	ARM Cortex A-53	Marvell
legacy MD5	600K	543K	748K	383k
HMAC-MD5	463K	415K	864K	438k
HMAC-SHA224	276K	245K	357K	150k
CMAC (AES)	576K	412K	614K	246k
GMAC (AES)	681K	1362K	2193K	453k
Poly1305 (ChaCha20)	335K	379K	580K	273k

The table below shows latency in terms of number of CPU cycles per byte (cpb) when processing a 48-byte NTP payload.

Algorithm	PPC74xx	ARM Cortex-A9	ARM Cortex A-53	Marvell
legacy MD5	52.1	38.4	33.4	65.3
HMAC-MD5	67.4	50.3	29.0	57.1
HMAC-SHA224	113.3	85.2	70.1	166.5
CMAC (AES)	54.2	50.5	40.7	101.2
GMAC (AES)	50.0	15.3	11.4	55.1
Poly1305 (ChaCha20)	93.1	55.0	43.1	91.7

## 6. Security Considerations

The MD5 (key||message) "message authentication code" specified in [RFC5905] is vulnerable to length extension attacks, and uses the insecure MD5 hash function, and therefore MUST be deprecated.

Therefore, we consider hash-based MACs (HMAC-MD5, HMAC-SHA224), and cipher-based MACs (CMAC-AES, Poly1305 (ChaCha20)). The upper bound on the security level provided by any MAC against brute-force attacks is  $\min(\text{key-length}, \text{tag-length})$ . The security of these MACs can be worse but not better than this bound. All MAC algorithms we consider have comparable key-lengths and output tag-lengths. So the advantage of an adversary that wishes to forge a MAC is lower-bounded by  $1/2^{\{128\}}$ .

Assume that an adversary can obtain a valid MAC for  $q$  distinct messages. Then the table below describes the advantage of an adversary that wishes to forge a MAC in terms of number of queries ( $q$ ) it launches.

Algorithm	Advantage
HMAC-MD5 [MB]	$q^2/2^{128}$
HMAC-SHA224 [BCK]	$q^2/2^{224}$
CMAC (AES) [IK]	$q^2/2^{128}$
GMAC (AES) [IOM]	$q^2/2^{128}$
Poly1305 (ChaCha20) [DJB]	$\{e^{\{q^2\}/\{2^{129}\}}\}/2^{103}$

Poly1305 can easily handle up to  $q=2^{64}$  but security degrades pretty rapidly after that.

However, the bounds in the table above are somewhat optimistic, for the following reasons.

1. GMAC has an initialization vector (IV) that [RFC4106] allows to be  $1 \leq \text{len}(\text{IV}) \leq 2^{64}-1$ . Per [RFC4106], implementations are optimized to handle a 12-octet IV. With a 12-octet IV, the total number of message invocations is bound to  $2^{48}$ . Moreover, if the IV is reused even once (for the same secret authentication key and different input messages), then [Joux] shows that the secret authentication key can easily be recovered by the adversary. Notice that this attack is even stronger than a message forgery because it recovers the authentication key. This is known as nonce-reuse vulnerability.
2. The other three algorithms evaluated here do not suffer from nonce reuse vulnerabilities where an adversary can recover the authentication key if the nonce is reused just once.
3. The table above suggests that for CMAC, the total number of invocations of the MAC is limited to  $2^{64}$ . However, [NIST-CMAC] recommends, to be on the safe side, that the total number of invocations of the block cipher algorithm during the lifetime of the key is limited to  $2^{48}$ .

#### 6.1. Why is GMAC not suitable for NTP?

[Joux] showed that for GMAC-AES, if the IV is repeated just once, then the authentication key can be fully recovered. None of the other algorithms evaluated here have this vulnerability. Thus, for

GMAC-AES to be secure, we need to make sure that IV is never repeated.

[NIST-GMAC] recommends constructing the 12-byte IV used in GMAC by concatenating a fixed 4-byte salt value concatenate with a variable 8-byte nonce i.e.  $IV = (\text{salt} || \text{nonce})$ . Here salt is an implicit value established when a session is established, remains fixed for all exchanges in a session (i.e. for all invocations that use the same authentication key) between the sender and the receiver. Meanwhile, the nonce is freshly generated for each authenticated message.

Because NTP servers do not keep per-client state, the nonce can not be a sequential value. Instead, this nonce must be randomly generated 8-bytes value chosen freshly for each authenticated message. According to birthday bound, the nonce value will be repeated, with high probability, after  $2^{32}$  messages sent in a given association. This leads to a repeated IV value and to [Joux]'s attack. Thus, to prevent repeated nonces, we would need to require the authentication key to be refreshed for the association after  $2^{32}$  messages.

On one hand,  $2^{32}$  is a lot of queries for an honest client, assuming that the client queries once per minute (which is NTP's minimum polling interval [RFC5905]). On the other hand, a man-in-the-middle (MiTM) can quickly and easily exhaust this number by replaying old authenticated queries to the NTP server.

The main problem here is that NTP lacks an explicit in-band key refresh mechanism that can be invoked automatically (without operator intervention). And a key refresh mechanism is unlikely to be adopted as it would allow denial-of-service (DoS) attacks. The state less nature makes NTP resilient against DoS attacks.

Even if there was a method by which key-refresh could be performed, there is an additional problem. An NTP server does not keep per-client state. Therefore, it cannot keep track of the number of messages it sent in a given association. One idea is to have the client keep this state, and then send an authenticated request for a key refresh. However, a man-in-the-middle could replay old authenticated queries to the NTP server, and then intercept the server's response before they reach the legitimate client. In this case, the client would never know when to ask for a key refresh.

Alternatively, the server could maintain a global counter (since it can't afford to keep per client counter). And after  $2^{32}$  messages, it can refresh the keys with all its clients. However, a man-in-the-

middle could exhaust this number quickly and the server will have to refresh keys with all the clients very frequently.

Thus, we conclude that a scheme that requires refreshing the key after  $2^{32}$  client queries is not a good idea at all.

Even in the absence of a man-in-the-middle, there is also the problem of multiple servers using the same authentication key. The salt could be used to distinguish IVs across different client/server associations that use the same authentication key. However, this brings us back to the original key management problem. One way to deal with this is to choose the 4-byte salt at random. However, this gives rise to a birthday bound of  $2^{16} = 65,000$  unique IVs. If we consider 20,000 stratum 3 clients synchronizing to three stratum 2 servers each, all of which are in the same organization and share the same symmetric key, we get very close to the birthday bound. This is another disadvantage of using GMAC with NTP.

#### 7. Use HMAC or CMAC instead

1. CMAC seems to be the next best choice. Leaving out GMAC, it has the best performance with and without hardware support. It is not vulnerable to nonce misuse issues.
2. HMACs are inherently slower because of their structure and also in some cases because of lack of built-in hardware support.
3. On the other hand, it is much easier to get the right implementation for HMAC compared to CMAC.

#### 8. GMAC-SIV - Another Potential MAC Candidate

GMAC-SIV is another possible MAC candidate, which claims to be nonce-misuse resistant [SIV]. There is an IETF Internet draft for the standardization of GCM-SIV AEAD mode.

In terms of security, GCM-SIV (AEAD) achieves usual notion of nonce-based security of an authenticated encryption mode as long as a unique nonce is used per authentication key per message. If, however, the nonce is reused authenticity is still retained (unlike in GMAC).

But there is not many implementations for GCM-SIV available except for the one from the authors. We customized this code for authentication only mode GMAC-SIV and run it on an x86\_64, Intel(R) Xeon(R) CPU E5-2676 v3 @ 2.40GHz with one core CPU with AES-NI enabled. GMAC-SIV takes ~5.9 CPU cycles/byte to generate a tag of length 16 bytes on a 48-byte NTP payload. The performance efficiency

is far less than GMAC, but is slightly better than CMAC. CMAC, on the other hand is a standardized mode of operation and has several open source implementations.

## 9. Recommendations

From the tables we clearly see that GMAC(AES) has the best latency and throughput performance in both hardware and software implementations. It is freely available, and there is a flexibility of changing the underlying block-cipher. However there are several security problems surrounding the use of this mode, as highlighted above, so it is not recommended.

CMAC, on the other hand, is the next best choice in terms of performance and security. So we recommend the use of CMAC (AES).

AES-GCM-SIV: Nonce Misuse-Resistant Authenticated Encryption  
draft-irtf-cfrg-gcmsiv-09

Abstract

This memo specifies two authenticated encryption algorithms that are nonce misuse-resistant - that is that they do not fail catastrophically if a nonce is repeated.

Status of This Memo

This Internet-Draft is submitted in full conformance with the provisions of BCP 78 and BCP 79.

Internet-Drafts are working documents of the Internet Engineering Task Force (IETF). Note that other groups may also distribute working documents as Internet-Drafts. The list of current Internet-Drafts is at <https://datatracker.ietf.org/drafts/current/>.

Internet-Drafts are draft documents valid for a maximum of six months and may be updated, replaced, or obsoleted by other documents at any time. It is inappropriate to use Internet-Drafts as reference material or to cite them other than as "work in progress."

This Internet-Draft will expire on May 23, 2019.

## 1. Introduction

The concept of "Authenticated encryption with additional data" (AEAD [RFC5116]) couples confidentiality and integrity in a single operation, avoiding the risks of the previously common practice of using ad-hoc constructions of block-cipher and hash primitives. The most popular AEAD, AES-GCM [GCM], is seeing widespread use due to its attractive performance.

However, some AEADs (including AES-GCM) suffer catastrophic failures of confidentiality and/or integrity when two distinct messages are encrypted with the same key and nonce. While the requirements for AEADs specify that the pair of (key, nonce) shall only ever be used once, and thus prohibit this, in practice this is a worry.

Nonce misuse-resistant AEADs do not suffer from this problem. For this class of AEADs, encrypting two messages with the same nonce only discloses whether the messages were equal or not. This is the minimum amount of information that a deterministic algorithm can leak in this situation.

This memo specifies two nonce misuse-resistant AEADs: "AEAD\_AES\_128\_GCM\_SIV" and "AEAD\_AES\_256\_GCM\_SIV". These AEADs are designed to be able to take advantage of existing hardware support for AES-GCM and can decrypt within 5% of the speed of AES-GCM (for multi-kilobyte messages). Encryption is, perforce, slower than AES-GCM because two passes are required in order to achieve that nonce misuse-resistance property. However, measurements suggest that it can still run at two-thirds of the speed of AES-GCM.

We suggest that these AEADs be considered in any situation where nonce uniqueness cannot be guaranteed. This includes situations where there is no stateful counter or where such state cannot be guaranteed, as when multiple encryptors use the same key. As discussed in Section 9, it is RECOMMENDED to use this scheme with randomly chosen nonces.

## 2. Requirements Language

The key words "MUST", "MUST NOT", "REQUIRED", "SHALL", "SHALL NOT", "SHOULD", "SHOULD NOT", "RECOMMENDED", "MAY", and "OPTIONAL" in this document are to be interpreted as described in RFC 2119 [RFC2119].

## 3. POLYVAL

The GCM-SIV construction is similar to GCM: the block cipher is used in counter mode to encrypt the plaintext and a polynomial authenticator is used to provide integrity. The authenticator in GCM-SIV is called POLYVAL.

POLYVAL, like GHASH (the authenticator in AES-GCM, see [GCM] section 6.4), operates in a binary field of size  $2^{128}$ . The field is defined by the irreducible polynomial  $x^{128} + x^{127} + x^{126} + x^{121} + 1$ . The sum of any two elements in the field is the result of XORing them. The product of any two elements is calculated using standard (binary) polynomial multiplication followed by reduction modulo the irreducible polynomial.

We define another binary operation on elements of the field:  $\text{dot}(a, b)$ , where  $\text{dot}(a, b) = a * b * x^{-128}$ . The value of the field element  $x^{-128}$  is equal to  $x^{127} + x^{124} + x^{121} + x^{114} + 1$ . The result,  $\text{dot}(a, b)$ , of this multiplication is another field element.

Polynomials in this field are converted to and from 128-bit strings by taking the least-significant bit of the first byte to be the coefficient of  $x^0$ , the most-significant bit of the first byte to the coefficient of  $x^7$  and so on, until the most-significant bit of the last byte is the coefficient of  $x^{127}$ .

POLYVAL takes a field element,  $H$ , and a series of field elements  $X_1, \dots, X_s$ . Its result is  $S_s$ , where  $S$  is defined by the iteration  $S_0 = 0$ ;  $S_j = \text{dot}(S_{j-1} + X_j, H)$ , for  $j = 1..s$

We note that  $\text{POLYVAL}(H, X_1, X_2, \dots)$  is equal to  $\text{ByteReverse}(\text{GHASH}(\text{ByteReverse}(H) * x, \text{ByteReverse}(X_1), \text{ByteReverse}(X_2), \dots))$ , where  $\text{ByteReverse}$  is a function that reverses the order of 16 bytes. See Appendix A for a more detailed explanation.

#### 4. Encryption

AES-GCM-SIV encryption takes a 16- or 32-byte key-generating key, a 96-bit nonce, and variable-length plaintext & additional data byte-strings. It outputs an authenticated ciphertext that will be 16 bytes longer than the plaintext. Both encryption and decryption are only defined on inputs that are a whole number of bytes.

If the key-generating key is 16 bytes long then AES-128 is used throughout. Otherwise AES-256 is used throughout.

The first step of encryption is to generate per-nonce, message-authentication and message-encryption keys. The message-authentication key is 128-bit and the message-encryption key is either 128- (for AES-128) or 256-bit (for AES-256).

These keys are generated by encrypting a series of plaintext blocks that contain a 32-bit, little-endian counter followed by the nonce, and then discarding the second half of the resulting ciphertext. In the AES-128 case,  $128 + 128 = 256$  bits of key material need to be generated and, since encrypting each block yields 64 bits after discarding half, four blocks need to be encrypted. The counter values for these blocks are 0, 1, 2 and 3. For AES-256, six blocks are needed in total, with counter values 0 through 5 (inclusive).

In pseudocode form, where  $++$  indicates concatenation and  $x[:8]$  indicates taking only the first eight bytes from  $x$ :

```

func derive_keys(key_generating_key, nonce) {
    message_authentication_key =
        AES(key = key_generating_key,
            block = little_endian_uint32(0) ++ nonce)[:8] ++
        AES(key = key_generating_key,
            block = little_endian_uint32(1) ++ nonce)[:8]
    message_encryption_key =
        AES(key = key_generating_key,
            block = little_endian_uint32(2) ++ nonce)[:8] ++
        AES(key = key_generating_key,
            block = little_endian_uint32(3) ++ nonce)[:8]

    if bytelen(key_generating_key) == 32 {
        message_encryption_key +=
            AES(key = key_generating_key,
                block = little_endian_uint32(4) ++ nonce)[:8] ++
            AES(key = key_generating_key,
                block = little_endian_uint32(5) ++ nonce)[:8]
    }

    return message_authentication_key, message_encryption_key
}

```

Define the "length block" as a 16-byte value that is the concatenation of the 64-bit, little-endian encodings of `bytelen(additional_data) * 8` and `bytelen(plaintext) * 8`. Pad the plaintext and additional data with zeros until they are each a multiple of 16 bytes, the AES block size. Then `X_1`, `X_2`, ... (the series of field elements that are inputs to POLYVAL) are the concatenation of the padded additional data, the padded plaintext, and the length block.

Calculate `S_s = POLYVAL(message-authentication-key, X_1, X_2, ...)`. XOR the first twelve bytes of `S_s` with the nonce and clear the most-significant bit of the last byte. Encrypt the result with AES using the message-encryption key to produce the tag.

(It's worth highlighting a contrast with AES-GCM here: AES-GCM authenticates the encoded additional data and ciphertext, while AES-GCM-SIV authenticates the encoded additional data and `plaintext`.)

The encrypted plaintext is produced by using AES, with the message-encryption key, in counter mode (see [SP800-38A], section 6.5) on the unpadded plaintext. The initial counter block is the tag with the most-significant bit of the last byte set to one. The counter advances by incrementing the first 32 bits interpreted as an unsigned, little-endian integer, wrapping at  $2^{32}$ . The result of the

encryption is the encrypted plaintext (truncated to the length of the plaintext) followed by the tag.

In pseudo-code form, the encryption process can be expressed as:

```
func right_pad_to_multiple_of_16_bytes(input) {
    while (bytelen(input) % 16 != 0) {
        input = input ++ "\x00"
    }
    return input
}

func AES_CTR(key, initial_counter_block, in) {
    block = initial_counter_block

    output = ""
    while bytelen(in) > 0 {
        keystream_block = AES(key = key, block = block)
        block[0:4] = little_endian_uint32(
            read_little_endian_uint32(block[0:4]) + 1)

        todo = min(bytelen(in), bytelen(keystream_block))
        for j = 0; j < todo; j++ {
            output = output ++ (keystream_block[j] ^ in[j])
        }

        in = in[todo:]
    }

    return output
}

func encrypt(key_generating_key,
             nonce,
             plaintext,
             additional_data) {
    if bytelen(plaintext) > 2**36 {
        fail()
    }
    if bytelen(additional_data) > 2**36 {
        fail()
    }

    message_encryption_key, message_authentication_key =
        derive_keys(key_generating_key, nonce)

    length_block =
        little_endian_uint64(bytelen(additional_data) * 8) ++
}
```

```

        little_endian_uint64(bytelen(plaintext) * 8)
    padded_plaintext = right_pad_to_multiple_of_16_bytes(plaintext)
    padded_ad = right_pad_to_multiple_of_16_bytes(additional_data)
    S_s = POLYVAL(key = message_authentication_key,
                 input = padded_ad ++ padded_plaintext ++
                       length_block)
    for i = 0; i < 12; i++ {
        S_s[i] ^= nonce[i]
    }
    S_s[15] &= 0x7f
    tag = AES(key = message_encryption_key, block = S_s)

    counter_block = tag
    counter_block[15] |= 0x80
    return AES_CTR(key = message_encryption_key,
                  initial_counter_block = counter_block,
                  in = plaintext) ++
        tag
}

```

## 5. Decryption

Decryption takes a 16- or 32-byte key-generating key, a 96-bit nonce, and variable-length ciphertext & additional data byte-strings. It either fails, or outputs a plaintext that is 16 bytes shorter than the ciphertext.

To decrypt an AES-GCM-SIV ciphertext, first derive the message-encryption and message-authentication keys in the same manner as when encrypting.

If the ciphertext is less than 16 bytes or more than  $2^{36} + 16$  bytes, then fail. Otherwise split the input into the encrypted plaintext and a 16-byte tag. Decrypt the encrypted plaintext with the message-encryption key in counter mode, where the initial counter block is the tag with the most-significant bit of the last byte set to one. Advance the counter for each block in the same way as when encrypting. At this point the plaintext is unauthenticated and **MUST NOT** be output until the following tag confirmation is complete:

Pad the additional data and plaintext with zeros until they are each a multiple of 16 bytes, the AES block size. Calculate the length block and  $X_1$ ,  $X_2$ , ... as above and compute  $S_s = \text{POLYVAL}(\text{message-authentication-key}, X_1, X_2, \dots)$ . Compute the expected tag by XORing  $S_s$  and the nonce, clearing the most-significant bit of the last byte and encrypting with the message-encryption key. Compare the provided and expected tag values in constant time. Fail the

decryption if they do not match (and do not release the plaintext), otherwise return the plaintext.

In pseudo-code form, the decryption process can be expressed as:

```
func decrypt(key_generating_key,
            nonce,
            ciphertext,
            additional_data) {
    if bytelen(ciphertext) < 16 || bytelen(ciphertext) > 2**36 + 16 {
        fail()
    }
    if bytelen(additional_data) > 2**36 {
        fail()
    }

    message_encryption_key, message_authentication_key =
        derive_keys(key_generating_key, nonce)

    tag = ciphertext[bytelen(ciphertext)-16:]

    counter_block = tag
    counter_block[15] |= 0x80
    plaintext = AES_CTR(key = message_encryption_key,
                       initial_counter_block = counter_block,
                       in = ciphertext[:bytelen(ciphertext)-16])

    length_block =
        little_endian_uint64(bytelen(additional_data) * 8) ++
        little_endian_uint64(bytelen(plaintext) * 8)
    padded_plaintext = right_pad_to_multiple_of_16_bytes(plaintext)
    padded_ad = right_pad_to_multiple_of_16_bytes(additional_data)
    S_s = POLYVAL(key = message_authentication_key,
                 input = padded_ad ++ padded_plaintext ++
                 length_block)
    for i = 0; i < 12; i++ {
        S_s[i] ^= nonce[i]
    }
    S_s[15] &= 0x7f
    expected_tag = AES(key = message_encryption_key, block = S_s)

    xor_sum = 0
    for i := 0; i < bytelen(expected_tag); i++ {
        xor_sum |= expected_tag[i] ^ tag[i]
    }

    if xor_sum != 0 {
        fail()
    }

    return plaintext
}
```

## 6. AEADs

We define two AEADs, in the format of RFC 5116, that use AES-GCM-SIV: AEAD\_AES\_128\_GCM\_SIV and AEAD\_AES\_256\_GCM\_SIV. They differ only in the size of the AES key used.

The key input to these AEADs becomes the key-generating key. Thus AEAD\_AES\_128\_GCM\_SIV takes a 16-byte key and AEAD\_AES\_256\_GCM\_SIV takes a 32-byte key.

The parameters for AEAD\_AES\_128\_GCM\_SIV are then: K\_LEN is 16, P\_MAX is  $2^{36}$ , A\_MAX is  $2^{36}$ , N\_MIN and N\_MAX are 12 and C\_MAX is  $2^{36} + 16$ .

The parameters for AEAD\_AES\_256\_GCM\_SIV differ only in the key size: K\_LEN is 32, P\_MAX is  $2^{36}$ , A\_MAX is  $2^{36}$ , N\_MIN and N\_MAX are 12 and C\_MAX is  $2^{36} + 16$ .

## 7. Field operation examples

Polynomials in this document will be written as 16-byte values. For example, the sixteen bytes 010000000000000000000000000000492 would represent the polynomial  $x^{127} + x^{124} + x^{121} + x^{114} + 1$ , which is also the value of  $x^{-128}$  in this field.

If  $a = 66e94bd4ef8a2c3b884cfa59ca342b2e$  and  $b = ff000000000000000000000000000000$  then  $a + b = 99e94bd4ef8a2c3b884cfa59ca342b2e$ ,  $a * b = 37856175e9dc9df26ebc6d6171aa0ae9$  and  $\text{dot}(a, b) = ebe563401e7e91ea3ad6426b8140c394$ .

## 8. Worked example

Consider the encryption of the plaintext "Hello world" with the additional data "example" under key `ee8e1ed9ff2540ae8f2ba9f50bc2f27c` using AEAD\_AES\_128\_GCM\_SIV. The random nonce that we'll use for this example is `752abad3e0afb5f434dc4310`.

In order to generate the message-authentication and message-encryption keys, a counter is combined with the nonce to form four blocks. These blocks are encrypted with key given above:

Counter	Nonce	Ciphertext
00000000	752abad3e0afb5f434dc4310	-> 310728d9911f1f38c40e952ca83d093e
01000000	752abad3e0afb5f434dc4310	-> 37b24316c3fab9a046ae90952daa0450
02000000	752abad3e0afb5f434dc4310	-> a4c5ae624996327947920b2d2412474b
03000000	752abad3e0afb5f434dc4310	-> c100be4d7e2c6edd1efef004305able7

The latter halves of the ciphertext blocks are discarded and the remaining bytes are concatenated to form the per-message keys. Thus the message-authentication key is 310728d9911f1f3837b24316c3fab9a0 and the message-encryption key is a4c5ae6249963279c100be4d7e2c6edd.

The length block contains the encoding of the bit-lengths of the additional data and plaintext, respectively. The string "example" is seven characters, thus 56 bits (or 0x38 in hex). The string "Hello world" is 11 characters, or 88 = 0x58 bits. Thus the length block is 38000000000000000580000000000000.

The input to POLYVAL is the padded additional data, padded plaintext and then the length block. This is 6578616d706c650000000000000000048656c6c6f20776f726c640000000000380000000000000580000000000000, based on the ASCII encoding of "example" (6578616d706c65) and of "Hello world" (48656c6c6f20776f726c64).

Calling POLYVAL with the message-authentication key and the input above results in S\_s = ad7fcf0b5169851662672f3c5f95138f.

Before encrypting, the nonce is XORed in and the most-significant bit of the last byte is cleared. This gives d85575d8b1c630e256bb6c2c5f95130f because that bit happened to be one previously. Encrypting with the message-encryption key (using AES-128) gives the tag, which is 4fbcdeb7e4793f4ald7e4faa70100af1.

In order to form the initial counter block, the most-significant bit of the last byte of the tag is set to one. That doesn't result in a change in this example. Encrypting this with the message key (using AES-128) gives the first block of the keystream: 1551f2c1787e81deac9a99f139540ab5.

The final ciphertext is the result of XORing the plaintext with the keystream and appending the tag. That gives 5d349ead175ef6bldef6fd4fbcdeb7e4793f4ald7e4faa70100af1.

## 9. Security Considerations

AES-GCM-SIV decryption involves first producing an unauthenticated plaintext. This plaintext is vulnerable to manipulation by an attacker thus, if an implementation released some or all of the plaintext before authenticating it, other parts of a system may process malicious data as if it were authentic. AES-GCM might be less likely to lead implementations to do this because, there, the ciphertext is generally authenticated before, or concurrently with, the plaintext calculation. Therefore this text requires that implementations MUST NOT release unauthenticated plaintext. Thus system designers should consider memory limitations when picking the

size of AES-GCM-SIV plaintexts: large plaintexts may not fit in the available memory of some machines, tempting implementations to release unverified plaintext.

A detailed cryptographic analysis of AES-GCM-SIV appears in [AES-GCM-SIV] and the remainder of this section is a summary of that paper.

The AEADs defined in this document calculate fresh AES keys for each nonce. This allows a larger number of plaintexts to be encrypted under a given key. Without this step, AES-GCM-SIV encryption would be limited by the birthday bound like other standard modes (e.g., AES-GCM, AES-CCM [RFC3610], and AES-SIV [RFC5297]). This means that when  $2^{64}$  blocks have been encrypted overall, a distinguishing adversary, who is trying to break the confidentiality of the scheme, has an advantage of  $1/2$ . Thus, in order to limit the adversary's advantage to  $2^{-32}$ , at most  $2^{48}$  blocks can be encrypted overall. In contrast, by deriving fresh keys from each nonce, it is possible to encrypt a far larger number of messages and blocks with AES-GCM-SIV.

We stress that nonce-misuse resistant schemes guarantee that if a nonce repeats then the only security loss is that identical plaintexts will produce identical ciphertexts. Since this can also be a concern (as the fact that the same plaintext has been encrypted twice is revealed), we do not recommend using a fixed nonce as a policy. In addition, as we show below, better-than-birthday bounds are achieved by AES-GCM-SIV when the nonce repetition rate is low. Finally, as shown in [BHT18], there is a great security benefit in the multi-user/multi-key setting when each particular nonce is re-used by a small number of users only. We stress that the nonce misuse-resistance property is not intended to be coupled with intentional nonce-reuse; rather, such schemes provide the best possible security in the event of nonce reuse. Due to all of the above, it is RECOMMENDED that AES-GCM-SIV nonces be randomly generated.

Some example usage bounds for AES-GCM-SIV are given below. The adversary's advantage is the "AdvEnc" from [key-derive] and is colloquially the ability of an attacker to distinguish ciphertexts from random bit-strings. The bounds below limit this advantage to  $2^{-32}$ . For up to 256 uses of the same nonce and key (i.e., where one can assume that nonce misuse is no more than this bound), the following message limits should be respected (this assumes a short AAD, i.e. less than 64 bytes):

$2^{29}$  messages, where each plaintext is at most 1GiB

$2^{35}$  messages, where each plaintext is at most 128MiB

$2^{49}$  messages, where each plaintext is at most 1MiB

$2^{61}$  messages, where each plaintext is at most 16KiB

Suzuki et al [multi-birthday] show that even if nonces are selected uniformly at random, the probability that one or more values would be repeated 256 or more times is negligible until the number of nonces reaches  $2^{102}$ . (Specifically the probability is  $1/((2^{96})^{(255)}) * \text{Binomial}(q, 256)$ , where  $q$  is the number of nonces.) Since  $2^{102}$  is vastly greater than the limit on the number of plaintexts per key given above, we don't feel that this limit on the number of repeated nonces will be a problem. This also means that selecting nonces at random is a safe practice with AES-GCM-SIV. The bounds obtained for random nonces are as follows (as above, for these bounds the adversary's advantage is at most  $2^{-32}$ ):

$2^{32}$  messages, where each plaintext is at most 8GiB

$2^{48}$  messages, where each plaintext is at most 32MiB

$2^{64}$  messages, where each plaintext is at most 128KiB

For situations where, for some reason, an even higher number of nonce repeats is possible (e.g. in devices with very poor randomness), the message limits need to be reconsidered. Theorem 7 in [AES-GCM-SIV] contains more details but, for up to 1,024 repeats of each nonce, the limits would be (again assuming a short AAD, i.e. less than 64 bytes):

$2^{25}$  messages, where each plaintext is at most 1GiB

$2^{31}$  messages, where each plaintext is at most 128MiB

$2^{45}$  messages, where each plaintext is at most 1MiB

$2^{57}$  messages, where each plaintext is at most 16KiB

In addition to calculating fresh AES keys for each nonce, these AEADs also calculate fresh POLYVAL keys. Previous versions of GCM-SIV did not do this and, instead, used part of the AEAD's key as the POLYVAL key. Bleichenbacher pointed out that this allowed an attacker who controlled the AEAD key to force the POLYVAL key to be zero. If a user of this AEAD authenticated messages with a secret additional-data value then this would be insecure as the attacker could calculate a valid authenticator without knowing the input. This does not violate the standard properties of an AEAD as the additional data is not assumed to be confidential. However, we want these AEADs to be robust to plausible misuse and also to be drop-in replacements for

AES-GCM and so derive nonce-specific POLYVAL keys to avoid this issue.

We also wish to note that the probability of successful forgery increases with the number of attempts that an attacker is permitted. The advantage defined in [key-derive] and used above is specified in terms of the ability of an attacker to distinguish ciphertexts from random bit-strings. It thus covers both confidentiality and integrity and theorem 6.2 in [key-derive] shows that the advantage increases with the number of decryption attempts. (Although much more slowly than with the number of encryptions; the dependence on the number of decryption queries for forgery is actually only linear, not quadratic. The latter is an artifact of the bound in the paper not being tight.) If an attacker is permitted extremely large numbers of attempts then the tiny probability that any given attempt succeeds may sum to a non-trivial chance.

A security analysis of a similar scheme without nonce-based key derivation appears in [GCM-SIV] and a full analysis of the bounds when applying nonce-based key derivation appears in [key-derive]. A larger table of bounds and other information appears at [aes-gcm-siv-homepage].

The multi-user/multi-key security of AES-GCM-SIV was studied by [BHT18] who showed that security is almost like in the single user setting, as long as nonces do not repeat many times across many users. This is the case when nonces are chosen randomly.

## 10. IANA Considerations

IANA is requested to add two entries to the registry of AEAD algorithms: AEAD\_AES\_128\_GCM\_SIV and AEAD\_AES\_256\_GCM\_SIV, both referencing this document as their specification.

## Appendix A. The relationship between POLYVAL and GHASH

GHASH and POLYVAL both operate in  $GF(2^{128})$ , although with different irreducible polynomials: POLYVAL works modulo  $x^{128} + x^{127} + x^{126} + x^{121} + 1$  and GHASH works modulo  $x^{128} + x^7 + x^2 + x + 1$ . Note that these irreducible polynomials are the "reverse" of each other.

GHASH also has a different mapping between 128-bit strings and field elements. Where as POLYVAL takes the least-significant to most-significant bits of the first byte to be the coefficients of  $x^0$  to  $x^7$ , GHASH takes them to be the coefficients of  $x^7$  to  $x^0$ . This continues until, for the last byte, POLYVAL takes the least-significant to most-significant bits to be the coefficients of  $x^{120}$  to  $x^{127}$  while GHASH takes them to be the coefficients of  $x^{127}$  to  $x^{120}$ .

The combination of these facts means that it's possible to "convert" values between the two by reversing the order of the bytes in a 16-byte string. The differing interpretations of bit order takes care of reversing the bits within each byte and then reversing the

bytes does the rest. This may have a practical benefit for implementations that wish to implement both GHASH and POLYVAL.

In order to be clear which field a given operation is performed in, let `mulX_GHASH` be a function that takes a 16-byte string, converts it to an element of GHASH's field using GHASH's convention, multiplies it by `x` and converts back to a string. Likewise, let `mulX_POLYVAL` be a function that converts a 16-byte string to an element of POLYVAL's field using POLYVAL's convention, multiplies it by `x` and converts back.

Given the 16-byte string `01000000000000000000000000000000`, `mulX_GHASH` of that string is `00800000000000000000000000000000` and `mulX_POLYVAL` of that string is `02000000000000000000000000000000`. As a more general example, given `9c98c04df9387ded828175a92ba652d8`, `mulX_GHASH` of that string is `4e4c6026fc9c3ef6c140bad495d3296c` and `mulX_POLYVAL` of it is `3931819bf271fada0503eb52574ca5f2`.

Lastly, let `ByteReverse` be the function that takes a 16-byte string and returns a copy where the order of the bytes has been reversed.

Now GHASH and POLYVAL can be defined in terms of one another:

```
POLYVAL(H, X_1, ..., X_n) =
ByteReverse(GHASH(mulX_GHASH(ByteReverse(H)), ByteReverse(X_1), ...,
ByteReverse(X_n)))
```

```
GHASH(H, X_1, ..., X_n) =
ByteReverse(POLYVAL(mulX_POLYVAL(ByteReverse(H)), ByteReverse(X_1),
..., ByteReverse(X_n)))
```

As a worked example, let `H = 25629347589242761d31f826ba4b757b`, `X_1 = 4f4f95668c83dfb6401762bb2d01a262` and `X_2 = d1a24ddd2721d006bbe45f20d3c9f362`. `POLYVAL(H, X_1, X_2) = f7a3b47b846119fae5b7866cf5e5b77e`. If we wished to calculate this given only an implementation of GHASH then the key for GHASH would be `mulX_GHASH(ByteReverse(H)) = dcbaa5dd137c188ebb21492c23c9b112`. Then `ByteReverse(GHASH(dcb..., ByteReverse(X_1), ByteReverse(X_2))) = f7a3b47b846119fae5b7866cf5e5b77e`, as required.

In the other direction, `GHASH(H, X_1, X_2) = bd9b3997046731fb96251b91f9c99d7a`. If we wished to calculate this given only an implementation of POLYVAL then we would first calculate the key for POLYVAL, `mulX_POLYVAL(ByteReverse(H))`, which is `f6ea96744df0633aec8424b18e26c54a`. Then `ByteReverse(POLYVAL(f6ea..., ByteReverse(X_1), ByteReverse(X_2))) = bd9b3997046731fb96251b91f9c99d7a`.

## Appendix B. Additional comparisons with AES-GCM

Some functional properties also differ between AES-GCM and AES-GCM-SIV that are worth noting:

AES-GCM allows plaintexts to be encrypted in a streaming fashion, i.e. the beginning of the plaintext can be encrypted and transmitted before the entire message has been processed. AES-GCM-SIV requires two passes for encryption and so cannot do this.

AES-GCM allows a constant additional-data input to be precomputed in order to save per-message computation. AES-GCM-SIV varies the authenticator key based on the nonce and so does not permit this.

The performance for AES-GCM vs AES-GCM-SIV on small machines can be roughly characterised by the number of AES operations and the number of  $GF(2^{128})$  multiplications needed to process a message. Let  $a = (\text{bytelen}(\text{additional-data}) + 15) / 16$  and  $p = (\text{bytelen}(\text{plaintext}) + 15) / 16$ . Then AES-GCM requires  $p + 1$  AES operations and  $p + a + 1$  field multiplications.

Defined similarly, AES-GCM-SIV with AES-128 requires  $p + 5$  AES operations and  $p + a + 1$  field multiplications. With AES-256 that becomes  $p + 7$  AES operations.

With large machines, the available parallelism becomes far more important and such simple performance analysis is no longer representative. For such machines, we find that decryption of AES-GCM-SIV is only about 5% slower than AES-GCM, as long as the message is at least a couple of kilobytes. Encryption tends to run about two-thirds the speed because of the additional pass required.

### C.3. Counter wrap tests

The tests in this section use `AEAD_AES_256_GCM_SIV` and are crafted to test correct wrapping of the block counter.

```

Hash-Based Signatures  
draft-mcgrew-hash-sigs-15

Abstract

This note describes a digital signature system based on cryptographic hash functions, following the seminal work in this area of Lamport, Diffie, Winternitz, and Merkle, as adapted by Leighton and Micali in 1995. It specifies a one-time signature scheme and a general signature scheme. These systems provide asymmetric authentication without using large integer mathematics and can achieve a high security level. They are suitable for compact implementations, are relatively simple to implement, and naturally resist side-channel attacks. Unlike most other signature systems, hash-based signatures would still be secure even if it proves feasible for an attacker to build a quantum computer.

This document is a product of the Crypto Forum Research Group (CFRG) in the IRTF.

Status of This Memo

This Internet-Draft is submitted in full conformance with the provisions of BCP 78 and BCP 79.

Internet-Drafts are working documents of the Internet Engineering Task Force (IETF). Note that other groups may also distribute working documents as Internet-Drafts. The list of current Internet-Drafts is at <https://datatracker.ietf.org/drafts/current/>.

Internet-Drafts are draft documents valid for a maximum of six months and may be updated, replaced, or obsoleted by other documents at any time. It is inappropriate to use Internet-Drafts as reference material or to cite them other than as "work in progress."

This Internet-Draft will expire on July 11, 2019.

## 1. Introduction

One-time signature systems, and general purpose signature systems built out of one-time signature systems, have been known since 1979 [Merkle79], were well studied in the 1990s [USPTO5432852], and have benefited from renewed attention in the last decade. The characteristics of these signature systems are small private and public keys and fast signature generation and verification, but large signatures and moderately slow key generation (in comparison with RSA and ECDSA). Private keys can be made very small by appropriate key generation, for example, as described in Appendix A. In recent years there has been interest in these systems because of their post-quantum security and their suitability for compact verifier implementations.

This note describes the Leighton and Micali adaptation [USPTO5432852] of the original Lamport-Diffie-Winternitz-Merkle one-time signature system [Merkle79] [C:Merkle87][C:Merkle89a][C:Merkle89b] and general signature system [Merkle79] with enough specificity to ensure interoperability between implementations.

A signature system provides asymmetric message authentication. The key generation algorithm produces a public/private key pair. A message is signed by a private key, producing a signature, and a message/signature pair can be verified by a public key. A One-Time

Signature (OTS) system can be used to sign one message securely, but will become insecure if more than one is signed with the same public/private key pair. An N-time signature system can be used to sign N or fewer messages securely. A Merkle tree signature scheme is an N-time signature system that uses an OTS system as a component.

In the Merkle scheme, a binary tree of height  $h$  is used to hold  $2^h$  OTS key pairs. Each interior node of the tree holds a value which is the hash of the values of its two children nodes. The public key of the tree is the value of the root node (a recursive hash of the OTS public keys), while the private key of the tree is the collection of all the OTS private keys, together with the index of the next OTS private key to sign the next message with.

In this note we describe the Leighton-Micali Signature (LMS) system, which is a variant of the Merkle scheme, and a Hierarchical Signature System (HSS) built on top of it that can efficiently scale to larger numbers of signatures. In order to support signing a large number of messages on resource constrained systems, the Merkle tree can be subdivided into a number of smaller trees. Only the bottom-most tree is used to sign messages, while trees above that are used to sign the public keys of their children. For example, in the simplest case with 2 levels with both levels consisting of height  $h$  trees, the root tree is used to sign  $2^h$  trees with  $2^h$  OTS key pairs, and each second level tree has  $2^h$  OTS key pairs, for a total of  $2^{(2h)}$  bottom level key pairs, and so can sign  $2^{(2h)}$  messages. The advantage of this scheme is that only the active trees need to be instantiated, which saves both time (for key generation) and space (for key storage). On the other hand, using a multilevel signature scheme increases the size of the signature, as well as the signature verification time.

This note is structured as follows. Notes on postquantum cryptography are discussed in Section 1.1. Intellectual Property issues are discussed in Section 1.2. The notation used within this note is defined in Section 3, and the public formats are described in Section 3.3. The LM-OTS signature system is described in Section 4, and the LMS and HSS N-time signature systems are described in Section 5 and Section 6, respectively. Sufficient detail is provided to ensure interoperability. The rationale for the design decisions is given in Section 7. The IANA registry for these signature systems is described in Section 8. Security considerations are presented in Section 9. Comparison with another hash based signature algorithm (XMSS) is in Section 10.

This document represents the rough consensus of the CFRG.

### 1.1. CFRG Note on Post-Quantum Cryptography

All post-quantum algorithms documented by the Crypto Forum Research Group (CFRG) are today considered ready for experimentation and further engineering development (e.g., to establish the impact of performance and sizes on IETF protocols). However, at the time of writing, we do not have significant deployment experience with such algorithms.

Many of these algorithms come with specific restrictions, e.g., change of classical interface or less cryptanalysis of proposed parameters than established schemes. CFRG has consensus that all documents describing post-quantum technologies include the above paragraph and a clear additional warning about any specific restrictions, especially as those might affect use or deployment of the specific scheme. That guidance may be changed over time via document updates.

Additionally, for LMS:

CFRG consensus is that we are confident in the cryptographic security of the signature schemes described in this document against quantum computers, given the current state of the research community's knowledge about quantum algorithms. Indeed, we are confident that the security of a significant part of the Internet could be made dependent on the signature schemes defined in this document, if developers take care of the following.

In contrast to traditional signature schemes, the signature schemes described in this document are stateful, meaning the secret key changes over time. If a secret key state is used twice, no cryptographic security guarantees remain. In consequence, it becomes feasible to forge a signature on a new message. This is a new property that most developers will not be familiar with and requires careful handling of secret keys. Developers should not use the schemes described here except in systems that prevent the reuse of secret key states.

Note that the fact that the schemes described in this document are stateful also implies that classical APIs for digital signatures cannot be used without modification. The API MUST be able to handle a secret key state; in particular, this means that the API MUST allow to return an updated secret key state.

## 1.2. Intellectual Property

This draft is based on U.S. patent 5,432,852, which was issued over twenty years ago and is thus expired.

### 1.2.1. Disclaimer

This document is not intended as legal advice. Readers are advised to consult with their own legal advisers if they would like a legal interpretation of their rights.

The IETF policies and processes regarding intellectual property and patents are outlined in [RFC3979] and [RFC4879] and at <https://datatracker.ietf.org/ipr/about>.

## 1.3. Conventions Used In This Document

The key words "MUST", "MUST NOT", "REQUIRED", "SHALL", "SHALL NOT", "SHOULD", "SHOULD NOT", "RECOMMENDED", "MAY", and "OPTIONAL" in this document are to be interpreted as described in [RFC2119].

## 2. Interface

The LMS signing algorithm is stateful; it modifies and updates the private key as a side effect of generating a signature. Once a particular value of the private key is used to sign one message, it MUST NOT be used to sign another.

The key generation algorithm takes as input an indication of the parameters for the signature system. If it is successful, it returns both a private key and a public key. Otherwise, it returns an indication of failure.

The signing algorithm takes as input the message to be signed and the current value of the private key. If successful, it returns a signature and the next value of the private key, if there is such a value. After the private key of an N-time signature system has signed N messages, the signing algorithm returns the signature and an indication that there is no next value of the private key that can be used for signing. If unsuccessful, it returns an indication of failure.

The verification algorithm takes as input the public key, a message, and a signature, and returns an indication of whether or not the signature and message pair is valid.

A message/signature pair is valid if the signature was returned by the signing algorithm upon input of the message and the private key

corresponding to the public key; otherwise, the signature and message pair is not valid with probability very close to one.

### 3. Notation

#### 3.1. Data Types

Bytes and byte strings are the fundamental data types. A single byte is denoted as a pair of hexadecimal digits with a leading "0x". A byte string is an ordered sequence of zero or more bytes and is denoted as an ordered sequence of hexadecimal characters with a leading "0x". For example, 0xe534f0 is a byte string with a length of three. An array of byte strings is an ordered set, indexed starting at zero, in which all strings have the same length.

Unsigned integers are converted into byte strings by representing them in network byte order. To make the number of bytes in the representation explicit, we define the functions `u8str(X)`, `u16str(X)`, and `u32str(X)`, which take a non-negative integer `X` as input and return one, two, and four byte strings, respectively. We also make use of the function `strTou32(S)`, which takes a four-byte string `S` as input and returns a non-negative integer; the identity `u32str(strTou32(S)) = S` holds for any four-byte string `S`.

##### 3.1.1. Operators

When `a` and `b` are real numbers, mathematical operators are defined as follows:

`^` : `a ^ b` denotes the result of `a` raised to the power of `b`

`*` : `a * b` denotes the product of `a` multiplied by `b`

`/` : `a / b` denotes the quotient of `a` divided by `b`

`%` : `a % b` denotes the remainder of the integer division of `a` by `b` (with `a` and `b` being restricted to integers in this case)

`+` : `a + b` denotes the sum of `a` and `b`

`-` : `a - b` denotes the difference of `a` and `b`

`AND` : `a AND b` denotes the bitwise AND of the two nonnegative integers `a` and `b` (represented in binary notation)

The standard order of operations is used when evaluating arithmetic expressions.

When  $B$  is a byte and  $i$  is an integer, then  $B \gg i$  denotes the logical right-shift operation by  $i$  bit positions. Similarly,  $B \ll i$  denotes the logical left-shift operation.

If  $S$  and  $T$  are byte strings, then  $S || T$  denotes the concatenation of  $S$  and  $T$ . If  $S$  and  $T$  are equal length byte strings, then  $S \text{ AND } T$  denotes the bitwise logical and operation.

The  $i$ -th element in an array  $A$  is denoted as  $A[i]$ .

### 3.1.2. Functions

If  $r$  is a non-negative real number, then we define the following functions:

`ceil(r)` : returns the smallest integer greater than or equal to  $r$

`floor(r)` : returns the largest integer less than or equal to  $r$

`lg(r)` : returns the base-2 logarithm of  $r$

### 3.1.3. Strings of $w$ -bit elements

If  $S$  is a byte string, then `byte(S, i)` denotes its  $i$ -th byte, where the index starts at 0 at the left. Hence, `byte(S, 0)` is the leftmost byte of  $S$ , `byte(S, 1)` is the second byte at the left and (assuming  $S$  is  $n$  bytes long) `byte(S, n-1)` is the rightmost byte of  $S$ . In addition, `bytes(S, i, j)` denotes the range of bytes from the  $i$ -th to the  $j$ -th byte, inclusive. For example, if  $S = 0x02040608$ , then `byte(S, 0)` is `0x02` and `bytes(S, 1, 2)` is `0x0406`.

A byte string can be considered to be a string of  $w$ -bit unsigned integers; the correspondence is defined by the function `coef(S, i, w)` as follows:

If  $S$  is a string,  $i$  is a positive integer, and  $w$  is a member of the set  $\{ 1, 2, 4, 8 \}$ , then `coef(S, i, w)` is the  $i$ -th,  $w$ -bit value, if  $S$  is interpreted as a sequence of  $w$ -bit values. That is,

$$\text{coef}(S, i, w) = (2^w - 1) \text{ AND} \\ ( \text{byte}(S, \text{floor}(i * w / 8)) \gg \\ (8 - (w * (i \% (8 / w)) + w)) )$$

#### 4. LM-OTS One-Time Signatures

This section defines LM-OTS signatures. The signature is used to validate the authenticity of a message by associating a secret private key with a shared public key. These are one-time signatures; each private key **MUST** be used at most one time to sign any given message.

As part of the signing process, a digest of the original message is computed using the cryptographic hash function  $H$  (see Section 4.1), and the resulting digest is signed.

In order to facilitate its use in an  $N$ -time signature system, the LM-OTS key generation, signing, and verification algorithms all take as input parameters  $I$  and  $q$ . The parameter  $I$  is a 16 byte string, which indicates which Merkle tree this LM-OTS is used with. The parameter  $q$  is a 32 bit integer which indicates the leaf of the Merkle tree where the OTS public key appears. These parameters are used as part of the security string, as listed in Section 7.1. When the LM-OTS signature system is used outside of an  $N$ -time signature system, the value  $I$  **MAY** be used to differentiate this one time signatures from others; however the value  $q$  **MUST** be set to the all-zero value.

##### 4.1. Parameters

The signature system uses the parameters  $n$  and  $w$ , which are both positive integers. The algorithm description also makes use of the internal parameters  $p$  and  $ls$ , which are dependent on  $n$  and  $w$ . These parameters are summarized as follows:

$n$  : the number of bytes of the output of the hash function

w : the width (in bits) of the Winternitz coefficients; that is, the number of bits from the hash or checksum that is used with a single Winternitz chain. It is a member of the set { 1, 2, 4, 8 }

p : the number of n-byte string elements that make up the LM-OTS signature. This is a function of n and w; the values for the defined parameter sets are listed in Table 1; it can also be computed by the algorithm given in Appendix B.

ls : the number of left-shift bits used in the checksum function Cksm (defined in Section 4.4)

H : a second-preimage-resistant cryptographic hash function that accepts byte strings of any length, and returns an n-byte string

For more background on the cryptographic security requirements on H, see the Section 9.

The value of n is determined by the hash function selected for use as part of the LM-OTS algorithm; the choice of this value has a strong effect on the security of the system. The parameter w determines the length of the Winternitz chains computed as a part of the OTS signature (which involve  $2^w-1$  invocations of the hash function); it has little effect on security. Increasing w will shorten the signature, but at a cost of a larger computation to generate and verify a signature. The values of p and ls are dependent on the choices of the parameters n and w, as described in Appendix B. A table illustrating various combinations of n, w, p and ls, along with the resulting signature length, is provided in Table 1.

The value of w describes a space/time trade-off; increasing the value of w will cause the signature to shrink (by decreasing the value of p) while increasing the amount of time needed to perform operations with it (generate the public key, generate and verify the signature); in general, the LM-OTS signature is  $4+n*(p+1)$  bytes long, and public key generation will take  $p*(2^w-1)+1$  hash computations (and signature generation and verification will take approximately half that on average).

Parameter Set Name	H	n	w	p	ls	sig_len
LMOTS_SHA256_N32_W1	SHA256	32	1	265	7	8516
LMOTS_SHA256_N32_W2	SHA256	32	2	133	6	4292
LMOTS_SHA256_N32_W4	SHA256	32	4	67	4	2180
LMOTS_SHA256_N32_W8	SHA256	32	8	34	0	1124

Table 1

Here SHA256 denotes the SHA-256 hash function defined in NIST standard [FIPS180].

#### 4.2. Private Key

The format of the LM-OTS private key is an internal matter to the implementation, and this document does not attempt to define it. One possibility is that the private key may consist of a typecode indicating the particular LM-OTS algorithm, an array  $x[]$  containing  $p$   $n$ -byte strings, and the 16-byte string  $I$  and the 4 byte string  $q$ . This private key MUST be used to sign (at most) one message. The following algorithm shows pseudocode for generating a private key.

Algorithm 0: Generating a Private Key

1. retrieve the values of  $q$  and  $I$  (the 16-byte identifier of the LMS public/private keypair) from the LMS tree that this LM-OTS private key will be used with
2. set type to the typecode of the algorithm
3. set  $n$  and  $p$  according to the typecode and Table 1
4. compute the array  $x$  as follows:
 

```
for ( i = 0; i < p; i = i + 1 ) {
    set x[i] to a uniformly random n-byte string
}
```
5. return  $u32str(type) || I || u32str(q) || \begin{matrix} x[0] \\ x[p-1] \end{matrix} || x[1] || \dots$

An implementation MAY use a pseudorandom method to compute  $x[i]$ , as suggested in [Merkle79], page 46. The details of the pseudorandom method do not affect interoperability, but the cryptographic strength

MUST match that of the LM-OTS algorithm. Appendix A provides an example of a pseudorandom method for computing the LM-OTS private key.

#### 4.3. Public Key

The LM-OTS public key is generated from the private key by iteratively applying the function  $H$  to each individual element of  $x$ , for  $2^w - 1$  iterations, then hashing all of the resulting values.

The public key is generated from the private key using the following algorithm, or any equivalent process.

Algorithm 1: Generating a One Time Signature Public Key From a Private Key

1. set type to the typecode of the algorithm
2. set the integers  $n$ ,  $p$ , and  $w$  according to the typecode and Table 1
3. determine  $x$ ,  $I$  and  $q$  from the private key
4. compute the string  $K$  as follows:
 

```
for ( i = 0; i < p; i = i + 1 ) {
    tmp = x[i]
    for ( j = 0; j < 2^w - 1; j = j + 1 ) {
        tmp = H(I || u32str(q) || u16str(i) || u8str(j) || tmp)
    }
    y[i] = tmp
}
K = H(I || u32str(q) || u16str(D_PBLC) || y[0] || ... || y[p-1])
```
5. return  $u32str(\text{type}) || I || u32str(q) || K$

where  $D\_PBLC$  is the fixed two byte value  $0x8080$ , which is used to distinguish the last hash from every other hash in this system.

The public key is the value returned by Algorithm 1.

#### 4.4. Checksum

A checksum is used to ensure that any forgery attempt that manipulates the elements of an existing signature will be detected. This checksum is needed because an attacker can freely advance any of the Winternitz chains. That is, if this checksum were not present, then an attacker who could find a hash that has every digit larger than the valid hash could replace it (and adjust the Winternitz chains). The security property that it provides is detailed in

Section 9. The checksum function `Cksm` is defined as follows, where `S` denotes the `n`-byte string that is input to that function, and the value `sum` is a 16-bit unsigned integer:

Algorithm 2: Checksum Calculation

```
sum = 0
for ( i = 0; i < (n*8/w); i = i + 1 ) {
    sum = sum + (2^w - 1) * coef(S, i, w)
}
return (sum << ls)
```

`ls` is the parameter that shifts the significant bits of the checksum into the positions that will actually be used by the `coef` function when encoding the digits of the checksum. The actual `ls` parameter is a function of the `n` and `w` parameters; the values for the currently defined parameter sets is shown in table 1. It is calculated by the algorithm given in Appendix B.

Because of the left-shift operation, the rightmost bits of the result of `Cksm` will often be zeros. Due to the value of `p`, these bits will not be used during signature generation or verification.

#### 4.5. Signature Generation

The LM-OTS signature of a message is generated by first prepending the LMS key identifier `I`, the LMS leaf identifier `q`, the value `D_MESG` (0x8181) and the randomizer `C` to the message, then computing the hash, and then concatenating the checksum of the hash to the hash itself, then considering the resulting value as a sequence of `w`-bit values, and using each of the `w`-bit values to determine the number of times to apply the function `H` to the corresponding element of the private key. The outputs of the function `H` are concatenated together and returned as the signature. The pseudocode for this procedure is shown below.

Algorithm 3: Generating a One Time Signature From a Private Key and a Message

1. set type to the typecode of the algorithm
2. set n, p, and w according to the typecode and Table 1
3. determine x, I and q from the private key
4. set C to a uniformly random n-byte string
5. compute the array y as follows:
 

```

Q = H(I || u32str(q) || u16str(D_MESG) || C || message)
for ( i = 0; i < p; i = i + 1 ) {
  a = coef(Q || Cksm(Q), i, w)
  tmp = x[i]
  for ( j = 0; j < a; j = j + 1 ) {
    tmp = H(I || u32str(q) || u16str(i) || u8str(j) || tmp)
  }
  y[i] = tmp
}

```
6. return u32str(type) || C || y[0] || ... || y[p-1]

Note that this algorithm results in a signature whose elements are intermediate values of the elements computed by the public key algorithm in Section 4.3.

The signature is the string returned by Algorithm 3. Section 3.3 specifies the typecode and more formally defines the encoding and decoding of the string.

#### 4.6. Signature Verification

In order to verify a message with its signature (an array of n-byte strings, denoted as y), the receiver must "complete" the chain of iterations of H using the w-bit coefficients of the string resulting from the concatenation of the message hash and its checksum. This computation should result in a value that matches the provided public key.

## Algorithm 4a: Verifying a Signature and Message Using a Public Key

1. if the public key is not at least four bytes long,  
return INVALID
2. parse pubkey, I, q, and K from the public key as follows:
  - a. pubkey = strTou32(first 4 bytes of public key)
  - b. set n according to the pubkey and Table 1; if the public key is not exactly 24 + n bytes long, return INVALID
  - c. I = next 16 bytes of public key
  - d. q = strTou32(next 4 bytes of public key)
  - e. K = next n bytes of public key
3. compute the public key candidate Kc from the signature, message, pubkey and the identifiers I and q obtained from the public key, using Algorithm 4b. If Algorithm 4b returns INVALID, then return INVALID.
4. if Kc is equal to K, return VALID; otherwise, return INVALID

Algorithm 4b: Computing a Public Key Candidate  $K_c$  from a Signature, Message, Signature Typecode  $pubtype$ , and identifiers  $I$ ,  $q$

1. if the signature is not at least four bytes long, return INVALID
  2. parse  $sigtype$ ,  $C$ , and  $y$  from the signature as follows:
    - a.  $sigtype = strTou32(\text{first 4 bytes of signature})$
    - b. if  $sigtype$  is not equal to  $pubtype$ , return INVALID
    - c. set  $n$  and  $p$  according to the  $pubtype$  and Table 1; if the signature is not exactly  $4 + n * (p+1)$  bytes long, return INVALID
    - d.  $C = \text{next } n \text{ bytes of signature}$
    - e.  $y[0] = \text{next } n \text{ bytes of signature}$   
 $y[1] = \text{next } n \text{ bytes of signature}$   
 $\dots$   
 $y[p-1] = \text{next } n \text{ bytes of signature}$
  3. compute the string  $K_c$  as follows
 

```

Q = H(I || u32str(q) || u16str(D_MESG) || C || message)
for ( i = 0; i < p; i = i + 1 ) {
  a = coef(Q || Cksm(Q), i, w)
  tmp = y[i]
  for ( j = a; j < 2^w - 1; j = j + 1 ) {
    tmp = H(I || u32str(q) || u16str(i) || u8str(j) || tmp)
  }
  z[i] = tmp
}
Kc = H(I || u32str(q) || u16str(D_PBLC) ||
      z[0] || z[1] || ... || z[p-1])
      
```
  4. return  $K_c$
5. Leighton-Micali Signatures

The Leighton-Micali Signature (LMS) method can sign a potentially large but fixed number of messages. An LMS system uses two cryptographic components: a one-time signature method and a hash function. Each LMS public/private key pair is associated with a perfect binary tree, each node of which contains an  $m$ -byte value, where  $m$  is the output length of the hash function. Each leaf of the tree contains the value of the public key of an LM-OTS public/private key pair. The value contained by the root of the tree is the LMS public key. Each interior node is computed by applying the hash function to the concatenation of the values of its children nodes.

Each node of the tree is associated with a node number, an unsigned integer that is denoted as `node_num` in the algorithms below, which is computed as follows. The root node has node number 1; for each node with node number  $N < 2^h$  (where  $h$  is the height of the tree), its left child has node number  $2*N$ , while its right child has node number  $2*N+1$ . The result of this is that each node within the tree will have a unique node number, and the leaves will have node numbers  $2^h$ ,  $(2^h)+1$ ,  $(2^h)+2$ , ...,  $(2^h)+(2^h)-1$ . In general, the  $j$ -th node at level  $i$  has node number  $2^i + j$ . The node number can conveniently be computed when it is needed in the LMS algorithms, as described in those algorithms.

### 5.1. Parameters

An LMS system has the following parameters:

$h$  : the height of the tree, and

$m$  : the number of bytes associated with each node.

$H$  : a second-preimage-resistant cryptographic hash function that accepts byte strings of any length, and returns an  $m$ -byte string.

There are  $2^h$  leaves in the tree.

The overall strength of the LMS signatures is governed by the weaker of the hash function used within the LM-OTS and the hash function used within the LMS system. In order to minimize the risk, these two hash functions SHOULD be the same (so that an attacker could not take advantage of the weaker hash function choice).

Name	H	m	h
LMS_SHA256_M32_H5	SHA256	32	5
LMS_SHA256_M32_H10	SHA256	32	10
LMS_SHA256_M32_H15	SHA256	32	15
LMS_SHA256_M32_H20	SHA256	32	20
LMS_SHA256_M32_H25	SHA256	32	25

Table 2

## 5.2. LMS Private Key

The format of the LMS private key is an internal matter to the implementation, and this document does not attempt to define it. One possibility is that it may consist of an array `OTS_PRIV[]` of  $2^h$  LM-OTS private keys, and the leaf number  $q$  of the next LM-OTS private key that has not yet been used. The  $q$ -th element of `OTS_PRIV[]` is generated using Algorithm 0 with the identifiers  $I, q$ . The leaf number  $q$  is initialized to zero when the LMS private key is created. The process is as follows:

Algorithm 5: Computing an LMS Private Key.

1. determine  $h$  and  $m$  from the typecode and Table 2.
2. set  $I$  to a uniformly random 16-byte string
3. compute the array `OTS_PRIV[]` as follows:  
for (  $q = 0; q < 2^h; q = q + 1$  ) {  
    `OTS_PRIV[q]` = LM-OTS private key with identifiers  $I, q$   
}
4.  $q = 0$

An LMS private key MAY be generated pseudorandomly from a secret value, in which case the secret value MUST be at least  $m$  bytes long, be uniformly random, and MUST NOT be used for any other purpose than the generation of the LMS private key. The details of how this process is done do not affect interoperability; that is, the public key verification operation is independent of these details. Appendix A provides an example of a pseudorandom method for computing an LMS private key.

The signature generation logic uses  $q$  as the next leaf to use, hence step 4 starts it off at the left-most one. Because the signature process increments  $q$  after the signature operation, the first signature will have  $q=0$ .

## 5.3. LMS Public Key

An LMS public key is defined as follows, where we denote the public key final hash value (namely, the  $K$  value computed in Algorithm 1) associated with the  $i$ -th LM-OTS private key as `OTS_PUB_HASH[i]`, with  $i$  ranging from 0 to  $(2^h)-1$ . Each instance of an LMS public/private key pair is associated with a balanced binary tree, and the nodes of that tree are indexed from 1 to  $2^{(h+1)}-1$ . Each node is associated with an  $m$ -byte string, and the string for the  $r$ -th node is denoted as `T[r]` and is defined as

```

if r >= 2^h:
    H(I || u32str(r) || u16str(D_LEAF) || OTS_PUB_HASH[r-2^h])
else
    H(I || u32str(r) || u16str(D_INTR) || T[2*r] || T[2*r+1])

```

where D\_LEAF is the fixed two byte value 0x8282, and D\_INTR is the fixed two byte value 0x8383, both of which are used to distinguish this hash from every other hash in this system.

When we have  $r \geq 2^h$ , then we are processing a leaf node (and thus hashing only a single LM-OTS public key). When we have  $r < 2^h$ , then we are processing an internal node, that is, a node with two child nodes that we need to combine.

The LMS public key is the string

```
u32str(type) || u32str(otstype) || I || T[1]
```

Section 3.3 specifies the format of the type variable. The value otstype is the parameter set for the LM-OTS public/private keypairs used. The value I is the private key identifier, and is the value used for all computations for the same LMS tree. The value T[1] can be computed via recursive application of the above equation, or by any equivalent method. An iterative procedure is outlined in Appendix C.

#### 5.4. LMS Signature

An LMS signature consists of

the number  $q$  of the leaf associated with the LM-OTS signature, as a four-byte unsigned integer in network byte order,

an LM-OTS signature,

a typecode indicating the particular LMS algorithm,

an array of  $h$   $m$ -byte values that is associated with the path through the tree from the leaf associated with the LM-OTS signature to the root.

Symbolically, the signature can be represented as

```
u32str(q) || lmots_signature || u32str(type) ||
path[0] || path[1] || path[2] || ... || path[h-1]
```

Section 3.3 specifies the typecode and more formally defines the format. The array for a tree with height  $h$  will have  $h$  values and

contains the values of the siblings of (that is, is adjacent to) the nodes on the path from the leaf to the root, where the sibling to node A is the other node which shares node A's parent. In the signature, 0 is counted from the bottom level of the tree, and so path[0] is the value of the node adjacent to leaf node q; path[1] is the second level node that is adjacent to leaf node q's parent, and so up the tree until we get to path[h-1], which is the value of the next-to-the-top level node that leaf node q does not reside in.

Below is a simple example of the authentication path for h=3 and q=2. The leaf marked OTS is the one time signature which is used to sign the actual message. The nodes on the path from the OTS public key to the root are marked with a \*, while the nodes that are used within the path array are marked with a \*\*. The values in the path array are those nodes which are siblings of the nodes on the path; path[0] is the leaf\*\* node that is adjacent to the OTS public key (which is the start of the path); path[1] is the T[4]\*\* node which is the sibling of the second node T[5]\* on the path, and path[2] is the T[3]\*\* node which is the sibling of the third node T[2]\* on the path.

The idea behind this authentication path is that it allows us to validate the OTS hash with using h path array values and hash computations. What the verifier does is recompute the hashes up the path; first, he hashes the given OTS and path[0] value, giving a tentative T[5]' value. Then, he hashes his path[1] and tentative T[5]' value to get a tentative T[2]' value. Then, he hashes that and the path[2] value to get a tentative Root' value. If that value is the known public key of the Merkle tree, then we can assume that the value T[2]' he got was the correct T[2] value in the original tree, and so the T[5]' value he got was the correct T[5] value in the original tree, and so the OTS public key is the same as in the original, and hence is correct.

#### 5.4.1. LMS Signature Generation

To compute the LMS signature of a message with an LMS private key, the signer first computes the LM-OTS signature of the message using the leaf number of the next unused LM-OTS private key. The leaf number  $q$  in the signature is set to the leaf number of the LMS private key that was used in the signature. Before releasing the signature, the leaf number  $q$  in the LMS private key MUST be incremented, to prevent the LM-OTS private key from being used again. If the LMS private key is maintained in nonvolatile memory, then the implementation MUST ensure that the incremented value has been stored before releasing the signature. The issue this tries to prevent is a scenario where a) we generate a signature, using one LM-OTS private key, and release it to the application, b) before we update the nonvolatile memory, we crash, and c) we reboot, and generate a second signature using the same LM-OTS private key; with two different signatures using the same LM-OTS private key, someone could potentially generate a forged signature of a third message.

The array of node values in the signature MAY be computed in any way. There are many potential time/storage tradeoffs that can be applied. The fastest alternative is to store all of the nodes of the tree and set the array in the signature by copying them; pseudocode to do so appears in Appendix D. The least storage intensive alternative is to recompute all of the nodes for each signature. Note that the details of this procedure are not important for interoperability; it is not necessary to know any of these details in order to perform the signature verification operation. The internal nodes of the tree need not be kept secret, and thus a node-caching scheme that stores only internal nodes can sidestep the need for strong protections.

Several useful time/storage tradeoffs are described in the 'Small-Memory LM Schemes' section of [USPTO5432852].

#### 5.4.2. LMS Signature Verification

An LMS signature is verified by first using the LM-OTS signature verification algorithm (Algorithm 4b) to compute the LM-OTS public key from the LM-OTS signature and the message. The value of that public key is then assigned to the associated leaf of the LMS tree, then the root of the tree is computed from the leaf value and the array path[] as described in Algorithm 6 below. If the root value matches the public key, then the signature is valid; otherwise, the signature fails.

## Algorithm 6: LMS Signature Verification

1. if the public key is not at least eight bytes long, return INVALID
2. parse pubkey, I, and T[1] from the public key as follows:
  - a. pubkey = strTou32(first 4 bytes of public key)
  - b. ots\_typecode = strTou32(next 4 bytes of public key)
  - c. set m according to pubkey, based on Table 2
  - d. if the public key is not exactly 24 + m bytes long, return INVALID
  - e. I = next 16 bytes of the public key
  - f. T[1] = next m bytes of the public key
3. compute the LMS Public Key Candidate Tc from the signature, message, identifier, pubkey and ots\_typecode using Algorithm 6a.
4. if Tc is equal to T[1], return VALID; otherwise, return INVALID

## Algorithm 6a: Computing an LMS Public Key Candidate from a Signature, Message, Identifier, and algorithm typecode

1. if the signature is not at least eight bytes long, return INVALID
2. parse sigtype, q, lmots\_signature, and path from the signature as follows:
  - a. q = strTou32(first 4 bytes of signature)
  - b. otssigtype = strTou32(next 4 bytes of signature)
  - c. if otssigtype is not the OTS typecode from the public key, return INVALID
  - d. set n, p according to otssigtype and Table 1; if the signature is not at least 12 + n \* (p + 1) bytes long, return INVALID
  - e. lmots\_signature = bytes 4 through 7 + n \* (p + 1) of signature
  - f. sigtype = strTou32(bytes 8 + n \* (p + 1)) through

- ```

11 + n * (p + 1) of signature)

```
- f. if sigtype is not the LM typecode from the public key,
 

```

return INVALID

```
  - g. set m, h according to sigtype and Table 2
  - h. if  $q \geq 2^h$  or the signature is not exactly
 

```

12 + n * (p + 1) + m * h bytes long,
return INVALID

```
  - i. set path as follows:
 

```

path[0] = next m bytes of signature
path[1] = next m bytes of signature
...
path[h-1] = next m bytes of signature

```
3. Kc = candidate public key computed by applying Algorithm 4b to the signature lmots\_signature, the message, and the identifiers I, q
  4. compute the candidate LMS root value Tc as follows:
 

```

node_num = 2^h + q
tmp = H(I || u32str(node_num) || u16str(D_LEAF) || Kc)
i = 0
while (node_num > 1) {
  if (node_num is odd):
    tmp = H(I || u32str(node_num/2) || u16str(D_INTR) || path[i] || tmp)
  else:
    tmp = H(I || u32str(node_num/2) || u16str(D_INTR) || tmp || path[i])
  node_num = node_num/2
  i = i + 1
}
Tc = tmp

```
  5. return Tc
6. Hierarchical signatures

In scenarios where it is necessary to minimize the time taken by the public key generation process, a Hierarchical N-time Signature System (HSS) can be used. This hierarchical scheme, which we describe in this section, uses the LMS scheme as a component. In HSS, we have a sequence of L LMS trees, where the public key for the first LMS tree is included in the public key of the HSS system, and where each LMS private key signs the next LMS public key, and where the last LMS private key signs the actual message. For example, if we have a three level hierarchy (L=3), then to sign a message, we would have:

The first LMS private key (level 0) signs a level 1 LMS public key.

The second LMS private key (level 1) signs a level 2 LMS public key.

The third LMS private key (level 2) signs the message.

The root of the level 0 LMS tree is contained in the HSS public key.

To verify the LMS signature, we would verify all the signatures:

We would verify that the level 1 LMS public key is correctly signed by the level 0 signature.

We would verify that the level 2 LMS public key is correctly signed by the level 1 signature.

We would verify that the message is correctly signed by the level 2 signature.

We would accept the HSS signature only if all the signatures validated.

During the signature generation process, we sign messages with the lowest (level  $L-1$ ) LMS tree. Once we have used all the leafs in that tree to sign messages, we would discard it, generate a fresh LMS tree, and sign it with the next (level  $L-2$ ) LMS tree (and when that is used up, recursively generate and sign a fresh level  $L-2$  LMS tree).

HSS, in essence, utilizes a tree of LMS trees. There is a single LMS tree at level 0 (the root). Each LMS tree (actually, the private key corresponding to the LMS tree) at level  $i$  is used to sign  $2^h$  objects (where  $h$  is the height of trees at level  $i$ ). If  $i < L-1$ , then each object will be another LMS tree (actually, the public key) at level  $i+1$ ; if  $i = L-1$ , we've reached the bottom of the HSS tree, and so each object is a message from the application. The HSS public key contains the public key of the LMS tree at the root, and an HSS signature is associated with a path from the root of the HSS tree to the leaf.

Compared to LMS, HSS has a much reduced public key generation time, as only the root tree needs to be generated prior to the distribution of the HSS public key. For example, a  $L=3$  tree (with  $h=10$  at each level) would have 1 level 0 LMS tree,  $2^{10}$  level 1 LMS trees (with each such level 1 public key signed by one of the 1024 level 0 LMS public keys), and  $2^{20}$  level 2 LMS trees. Only 1024 LMS public keys

need to be computed to generate the HSS public key (as you need to compute only the level 0 LMS tree to compute that value; you can, of course, decide to compute the initial level 1 and level 2 LMS trees). And, the  $2^{20}$  level 2 LMS trees can jointly sign a total of over a billion messages. In contrast, a single LMS tree that could sign a billion messages would require a billion OTS public keys to be computed first (even if  $h=30$  were allowed in a supported parameter set).

Each LMS tree within the hierarchy is associated with a distinct LMS public key, private key, signature, and identifier. The number of levels is denoted  $L$ , and is between one and eight, inclusive. The following notation is used, where  $i$  is an integer between 0 and  $L-1$  inclusive, and the root of the hierarchy is level 0:

`prv[i]` is the current LMS private key of the  $i$ -th level.

`pub[i]` is the current LMS public key of the  $i$ -th level, as described in Section 5.3.

`sig[i]` is the LMS signature of public key `pub[i+1]` generated using the private key `prv[i]`.

It is expected that the above arrays are maintained for the course of the HSS key. The contents of the `prv[]` array MUST be kept private; the `pub[]` and `sig[]` array may be revealed, should the implementation find that convenient.

In this section, we say that an  $N$ -time private key is exhausted when it has generated  $N$  signatures, and thus it can no longer be used for signing.

For  $i > 0$ , the values `prv[i]`, `pub[i]` and (for all values of  $i$ ) `sig[i]` will be updated over time, as private keys are exhausted, and replaced by newer keys.

When these keys pairs are updated (or initially generated before the first message is signed), then the LMS key generation processes outlined in sections Section 5.2 and Section 5.3 are performed. If the generated key pairs are for level  $i$  of the HSS hierarchy, then we store the public key in `pub[i]` and the private key in `prv[i]`. In addition, if  $i > 0$ , then we sign the generated public key with the LMS private key at level  $i-1$ , placing the signature into `sig[i-1]`. When the LMS key pair are generated, the key pair and the corresponding identifier MUST be generated independently of all other keypairs.

HSS allows  $L=1$ , in which case the HSS public key and signature formats are essentially the LMS public key and signature formats, prepended by a fixed field. Since HSS with  $L=1$  has very little overhead compared to LMS, all implementations MUST support HSS in order to maximize interoperability.

We specifically allow different LMS levels to use different parameter sets. For example, the 0-th LMS public key (the root) may use the LMS\_SHA256\_M32\_H15 parameter set, while the 1-th public key may use LMS\_SHA256\_M32\_H10. There are practical reasons to allow this; for one, the signer may decide to store parts of the 0-th LMS tree (that it needs to construct while computing the public key) to accelerate later operations. As the 0-th tree is never updated, these internal nodes will never need to be recomputed. In addition, during the signature generation operation, almost all the operations involved with updating the authentication path occurs with the bottom ( $L-1$ th) LMS public key; hence it may be useful to make the tree that implements that to be shorter.

A close reading of the HSS verification pseudocode would show that it would allow the parameters of the non-top LMS public keys to change over time; for example, the signer might initially have the 1-th LMS public key to use LMS\_SHA256\_M32\_H10, but when that tree is exhausted, the signer might replace it with LMS\_SHA256\_M32\_H15 LMS public key. While this would work with the example verification pseudocode, the signer MUST NOT change the parameter sets for a specific level. This prohibition is to support verifiers that may keep state over the course of several signature verifications.

### 6.1. Key Generation

The public key of the HSS scheme consists of the number of levels  $L$ , followed by `pub[0]`, the public key of the top level.

The HSS private key consists of `prv[0]`, ..., `prv[L-1]`, along with the associated `pub[0]`, ..., `pub[L-1]` and `sig[0]`, ..., `sig[L-2]` values. As stated earlier, the values of the `pub[]` and `sig[]` arrays need not be kept secret, but may be revealed. The value of `pub[0]` does not change (and, except for the index  $q$ , the value of `prv[0]` need not change), though the values of `pub[i]` and `prv[i]` are dynamic for  $i > 0$ , and are changed by the signature generation algorithm.

During the key generation, the public and private keys are initialized. Here is some pseudocode that explains the key generation logic

Algorithm 7: Generating an HSS keypair

1. generate an LMS key pair, as specified in sections 5.2 and 5.3, placing the private key into `priv[0]`, and the public key into `pub[0]`
2. for `i = 1` to `L-1` do {
  - generate an LMS key pair, placing the private key into `priv[i]` and the public key into `pub[i]`
  - `sig[i-1] = lms_signature( pub[i], priv[i-1] )`
3. return `u32str(L) || pub[0]` as the public key, and the `priv[]`, `pub[]` and `sig[]` arrays as the private key

In the above algorithm, each LMS public/private keypair generated MUST be generated independently.

Note that the value of the public key does not depend on the execution of step 2. As a result, an implementation may decide to delay step 2 until later, for example, during the initial signature generation operation.

## 6.2. Signature Generation

To sign a message using an HSS keypair, the following steps are performed:

If `priv[L-1]` is exhausted, then determine the smallest integer `d` such that all of the private keys `priv[d]`, `priv[d+1]`, ... , `priv[L-1]` are exhausted. If `d` is equal to zero, then the HSS key pair is exhausted, and it MUST NOT generate any more signatures. Otherwise, the key pairs for levels `d` through `L-1` must be regenerated during the signature generation process, as follows. For `i` from `d` to `L-1`, a new LMS public and private key pair with a new identifier is generated, `pub[i]` and `priv[i]` are set to those values, then the public key `pub[i]` is signed with `priv[i-1]`, and `sig[i-1]` is set to the resulting value.

The message is signed with `priv[L-1]`, and the value `sig[L-1]` is set to that result.

The value of the HSS signature is set as follows. We let `signed_pub_key` denote an array of octet strings, where `signed_pub_key[i] = sig[i] || pub[i+1]`, for `i` between 0 and `Nspk-1`, inclusive, where `Nspk = L-1` denotes the number of signed public

```
keys. Then the HSS signature is u32str(Nspk) ||
signed_pub_key[0] || ... || signed_pub_key[Nspk-1] || sig[Nspk].
```

Note that the number of `signed_pub_key` elements in the signature is indicated by the value `Nspk` that appears in the initial four bytes of the signature.

Here is some pseudocode of the above logic

Algorithm 8: Generating an HSS signature

1. If the message-signing key `prv[L-1]` is exhausted, regenerate that key pair, together with any parent key pairs that might be necessary.  
If the root key pair is exhausted, then the HSS key pair is exhausted and it MUST NOT generate any more signatures.

```
d = L
while (prv[d-1].q == 2^(prv[d-1].h)) {
    d = d - 1
    if (d == 0)
        return FAILURE
}
while (d < L) {
    create lms keypair pub[d], prv[d]
    sig[d-1] = lms_signature( pub[d], prv[d-1] )
    d = d + 1
}
```

2. sign the message  
`sig[L-1] = lms_signature( msg, prv[L-1] )`
3. Create the list of signed public keys  
`i = 0;`  
while (`i < L-1`) {  
    `signed_pub_key[i] = sig[i] || pub[i+1]`  
    `i = i + 1`  
}
4. return `u32str(L-1) || signed_pub_key[0] || ...`  
    `|| signed_pub_key[L-2] || sig[L-1]`

In the specific case of `L=1`, the format of an HSS signature is

```
u32str(0) || sig[0]
```

In the general case, the format of an HSS signature is

```

u32str(Nspk) || signed_pub_key[0] || ...
                || signed_pub_key[Nspk-1] || sig[Nspk]

```

which is equivalent to

```

u32str(Nspk) || sig[0] || pub[1] || ...
                || sig[Nspk-1] || pub[Nspk] || sig[Nspk]

```

### 6.3. Signature Verification

To verify a signature *S* and message using the public key *pub*, the following steps are performed:

The signature *S* is parsed into its components as follows:

```

Nspk = strTou32(first four bytes of S)
if Nspk+1 is not equal to the number of levels L in pub:
    return INVALID
for (i = 0; i < Nspk; i = i + 1) {
    siglist[i] = next LMS signature parsed from S
    publist[i] = next LMS public key parsed from S
}
siglist[Nspk] = next LMS signature parsed from S

key = pub
for (i = 0; i < Nspk; i = i + 1) {
    sig = siglist[i]
    msg = publist[i]
    if (lms_verify(msg, key, sig) != VALID):
        return INVALID
    key = msg
}
return lms_verify(message, key, siglist[Nspk])

```

Since the length of an LMS signature cannot be known without parsing it, the HSS signature verification algorithm makes use of an LMS signature parsing routine that takes as input a string consisting of an LMS signature with an arbitrary string appended to it, and returns both the LMS signature and the appended string. The latter is passed on for further processing.

### 6.4. Parameter Set Recommendations

As for guidance as to the number of LMS level, and the size of each, any discussion of performance is implementation specific. In general, the sole drawback for a single LMS tree is the time it takes

to generate the public key; as every LM-OTS public key needs to be generated, the time this takes can be substantial. For a two level tree, only the top level LMS tree and the initial bottom level LMS tree needs to be generated initially (before the first signature is generated); this will in general be significantly quicker.

To give a general idea on the trade-offs available, we include some measurements taken with the `github.com/cisco/hash-sigs` LMS implementation, taken on a 3.3 GHz Xeon processor, with threading enabled. We tried various parameter sets, all with  $W=8$  (which minimizes signature size, while increasing time). These are here to give a guideline as to what's possible; for the computational time, your mileage may vary, depending on the computing resources you have. The machine these tests were performed on does not have the SHA-256 extensions; you could possibly do significantly better.

| ParmSet | KeyGenTime | SigSize | KeyLifetime |
|---------|------------|---------|-------------|
| 15      | 6 sec      | 1616    | 30 seconds  |
| 20      | 3 min      | 1776    | 16 minutes  |
| 25      | 1.5 hour   | 1936    | 9 hours     |
| 15/10   | 6 sec      | 3172    | 9 hours     |
| 15/15   | 6 sec      | 3332    | 12 days     |
| 20/10   | 3 min      | 3332    | 12 days     |
| 20/15   | 3 min      | 3492    | 1 year      |
| 25/10   | 1.5 hour   | 3492    | 1 year      |
| 25/15   | 1.5 hour   | 3652    | 34 years    |

Table 3

**ParmSet:** this is the height of the Merkle tree(s); parameter sets listed as a single integer have  $L=1$ , and consist a single Merkle tree of that height; parameter sets with  $L=2$  are listed as  $x/y$ , with  $x$  being the height of the top level Merkle tree, and  $y$  being the bottom level.

**KeyGenTime:** the measured key generation time; that is, the time needed to generate the public private key pair.

SigSize: the size of a signature (in bytes)

KeyLifetime: the lifetime of a key, assuming we generated 1000 signatures per second. In practice, we're not likely to get anywhere close to 1000 signatures per second sustained; if you have a more appropriate figure for your scenario, this column is pretty easy to recompute.

As for signature generation or verification times, those are moderately insensitive to the above parameter settings (except for the Winternitz setting, and the number of Merkle trees for verification). Tests on the same machine (without multithreading) gave approximately 4msec to sign a short message, 2.6msec to verify; these tests used a two level ParmSet; a single level would approximately halve the verification time. All times can be significantly improved (by perhaps a factor of 8) by using a parameter set with  $W=4$ ; however that also about doubles the signature size.

## 7. Rationale

The goal of this note is to describe the LM-OTS, LMS and HSS algorithms following the original references and present the modern security analysis of those algorithms. Other signature methods are out of scope and may be interesting follow-on work.

We adopt the techniques described by Leighton and Micali to mitigate attacks that amortize their work over multiple invocations of the hash function.

The values taken by the identifier  $I$  across different LMS public/private key pairs are chosen randomly in order to improve security. The analysis of this method in [Fluhrer17] shows that we do not need uniqueness to ensure security; we do need to ensure that we don't have a large number of private keys that use the same  $I$  value. By randomly selecting 16 byte  $I$  values, the chance that, out of  $2^{64}$  private keys, 4 or more of them will use the same  $I$  value is negligible (that is, has probability less than  $2^{-128}$ ).

The reason 16 bytes  $I$  values were selected was to optimize the Winternitz hash chain operation. With the current settings, the value being hashed is exactly 55 bytes long (for a 32 byte hash function), which SHA-256 can hash in a single hash compression operation. Other hash functions may be used in future specifications; all the ones that we will be likely to support (SHA-512/256 and the various SHA-3 hashes) would work well with a 16-byte  $I$  value.

The signature and public key formats are designed so that they are relatively easy to parse. Each format starts with a 32-bit enumeration value that indicates the details of the signature algorithm and provides all of the information that is needed in order to parse the format.

The Checksum Section 4.4 is calculated using a non-negative integer "sum", whose width was chosen to be an integer number of w-bit fields such that it is capable of holding the difference of the total possible number of applications of the function H as defined in the signing algorithm of Section 4.5 and the total actual number. In the case that the number of times H is applied is 0, the sum is  $(2^w - 1) * (8*n/w)$ . Thus for the purposes of this document, which describes signature methods based on  $H = \text{SHA256}$  ( $n = 32$  bytes) and  $w = \{ 1, 2, 4, 8 \}$ , the sum variable is a 16-bit non-negative integer for all combinations of n and w. The calculation uses the parameter  $ls$  defined in Section 4.1 and calculated in Appendix B, which indicates the number of bits used in the left-shift operation.

### 7.1. Security String

To improve security against attacks that amortize their effort against multiple invocations of the hash function, Leighton and Micali introduce a "security string" that is distinct for each invocation of that function. Whenever this process computes a hash, the string being hashed will start with a string formed from the below fields. These fields will appear in fixed locations in the value we compute the hash of, and so we list where in the hash these fields would be present. These fields that make up this string are:

I - a 16-byte identifier for the LMS public/private key pair. It MUST be chosen uniformly at random, or via a pseudorandom process, at the time that a key pair is generated, in order to minimize the probability that any specific value of I be used for a large number of different LMS private keys. This is always bytes 0-15 of the value being hashed.

r - in the LMS N-time signature scheme, the node number r associated with a particular node of a hash tree is used as an input to the hash used to compute that node. This value is represented as a 32-bit (four byte) unsigned integer in network byte order. Either r or q (depending on the domain separation parameter) will be bytes 16-19 of the value being hashed.

q - in the LMS N-time signature scheme, each LM-OTS signature is associated with the leaf of a hash tree, and q is set to the leaf number. This ensures that a distinct value of q is used for each distinct LM-OTS public/private key pair. This value is

represented as a 32-bit (four byte) unsigned integer in network byte order. Either  $r$  or  $q$  (depending on the domain separation parameter) will be bytes 16-19 of the value being hashed.

$D$  - a domain separation parameter, which is a two byte identifier that takes on different values in the different contexts in which the hash function is invoked.  $D$  occurs in bytes 20, 21 of the value being hashed and takes on the following values:

$D\_PBLC = 0x8080$  when computing the hash of all of the iterates in the LM-OTS algorithm

$D\_MSG = 0x8181$  when computing the hash of the message in the LM-OTS algorithms

$D\_LEAF = 0x8282$  when computing the hash of the leaf of an LMS tree

$D\_INTR = 0x8383$  when computing the hash of an interior node of an LMS tree

$i$  - a value between 0 and 264; this is used in the LM-OTS scheme, when either computing the iterations of the Winternitz chain, or when using the suggested LM-OTS private key generation process. It is represented as a 16-bit (two-byte) unsigned integer in network byte order. If present, it occurs at bytes 20, 21 of the value being hashed.

$j$  - in the LM-OTS scheme,  $j$  is the iteration number used when the private key element is being iteratively hashed. It is represented as an 8-bit (one byte) unsigned integer and is present if  $i$  is a value between 0 and 264. If present, it occurs at bytes 22 to 21+n of the value being hashed.

$C$  - an  $n$ -byte randomizer that is included with the message whenever it is being hashed to improve security.  $C$  MUST be chosen uniformly at random, or via a pseudorandom process. It is present if  $D=D\_MSG$ , and it occurs at bytes 22 to 21+n of the value being hashed.

## 8. IANA Considerations

The Internet Assigned Numbers Authority (IANA) is requested to create two registries: one for OTS signatures, which includes all of the LM-OTS signatures as defined in Section 4, and one for Leighton-Micali Signatures, as defined in Section 5.

Additions to these registries require that a specification be documented in an RFC or another permanent and readily available reference in sufficient detail that interoperability between independent implementations is possible. IANA MUST verify that all applications for additions to these registries hve first been reviewed by the IRTF Crypto Forum Research Group (CFRG).

Each entry in the registry contains the following elements:

a short name, such as "LMS\_SHA256\_M32\_H10",

a positive number, and

a reference to a specification that completely defines the signature method test cases that can be used to verify the correctness of an implementation.

The numbers between 0xDDDDDDDD (decimal 3,722,304,989) and 0xFFFFFFFF (decimal 4,294,967,295) inclusive, will not be assigned by IANA, and are reserved for private use; no attempt will be made to prevent multiple sites from using the same value in different (and incompatible) ways [RFC2434].

The LM-OTS registry is as follows.

| Name                | Reference | Numeric Identifier |
|---------------------|-----------|--------------------|
| Reserved            |           | 0x00000000         |
| LMOTS_SHA256_N32_W1 | Section 4 | 0x00000001         |
| LMOTS_SHA256_N32_W2 | Section 4 | 0x00000002         |
| LMOTS_SHA256_N32_W4 | Section 4 | 0x00000003         |
| LMOTS_SHA256_N32_W8 | Section 4 | 0x00000004         |

Table 4

The LMS registry is as follows.

| Name               | Reference | Numeric Identifier |
|--------------------|-----------|--------------------|
| Reserved           |           | 0x0 - 0x4          |
| LMS_SHA256_M32_H5  | Section 5 | 0x00000005         |
| LMS_SHA256_M32_H10 | Section 5 | 0x00000006         |
| LMS_SHA256_M32_H15 | Section 5 | 0x00000007         |
| LMS_SHA256_M32_H20 | Section 5 | 0x00000008         |
| LMS_SHA256_M32_H25 | Section 5 | 0x00000009         |

Table 5

An IANA registration of a signature system does not constitute an endorsement of that system or its security.

The LM-OTS and the LMS registries currently occupy a disjoint set of values. This coincidence is a historical accident; the correctness of the system does not depend on this. IANA is not required to maintain this situation.

## 9. Security Considerations

The hash function H MUST have second preimage resistance: it must be computationally infeasible for an attacker that is given one message M to be able to find a second message M' such that  $H(M) = H(M')$ .

The security goal of a signature system is to prevent forgeries. A successful forgery occurs when an attacker who does not know the private key associated with a public key can find a message (distinct from all previously signed ones) and signature that is valid with that public key (that is, the Signature Verification algorithm applied to that signature and message and public key will return VALID). Such an attacker, in the strongest case, may have the ability to forge valid signatures for an arbitrary number of other messages.

LMS is provably secure in the random oracle model, where the hash compression function is considered the random oracle, as shown by [Fluhrer17]. Corollary 1 of that paper states:

If we have no more than  $2^{64}$  randomly chosen LMS private keys, allow the attacker access to a signing oracle and a SHA-256 hash

compression oracle, and allow a maximum of  $2^{120}$  hash compression computations, then the probability of an attacker being able to generate a single forgery against any of those LMS keys is less than  $2^{-129}$ .

Many of the objects within the public key and the signature start with a typecode. A verifier MUST check each of these typecodes, and a verification operation on a signature with an unknown type, or a type that does not correspond to the type within the public key MUST return INVALID. The expected length of a variable-length object can be determined from its typecode, and if an object has a different length, then any signature computed from the object is INVALID.

### 9.1. Hash Formats

The format of the inputs to the hash function H have the property that each invocation of that function has an input that is repeated by a small bounded number of other inputs (due to potential repeats of the I value), and in particular, will vary somewhere in the first 23 bytes of the value being hashed. This property is important for a proof of security in the random oracle model.

The formats used during key generation and signing (including the recommended pseudorandom key generation procedure in Appendix A):

|   |  |           |  |                |  |                     |  |               |
|---|--|-----------|--|----------------|--|---------------------|--|---------------|
| I |  | u32str(q) |  | u16str(i)      |  | u8str(j)            |  | tmp           |
| I |  | u32str(q) |  | u16str(D_PBLC) |  | y[0]                |  | ...    y[p-1] |
| I |  | u32str(q) |  | u16str(D_MESG) |  | C                   |  | message       |
| I |  | u32str(r) |  | u16str(D_LEAF) |  | OTS_PUB_HASH[r-2^h] |  |               |
| I |  | u32str(r) |  | u16str(D_INTR) |  | T[2*r]              |  | T[2*r+1]      |
| I |  | u32str(q) |  | u16str(i)      |  | u8str(0xff)         |  | SEED          |

Each hash type listed is distinct; at locations 20, 21 of the value being hashed, there exists either a fixed value D\_PBLC, D\_MESG, D\_LEAF, D\_INTR, or a 16 bit value i. These fixed values are distinct from each other, and are large (over 32768), while the 16 bit values of i are small (currently no more than 265; possibly being slightly larger if larger hash functions are supported); hence the range of possible values of i will not collide any of the D\_PBLC, D\_MESG, D\_LEAF, D\_INTR identifiers. The only other collision possibility is the Winternitz chain hash colliding with the recommended pseudorandom key generation process; here, at location 22 of the value being hashed, the Winternitz chain function has the value u8str(j), where j is a value between 0 and 254, while location 22 of the recommended pseudorandom key generation process has value 255.

For the Winternitz chaining function, D\_PBLC, and D\_MESG, the value of I || u32str(q) is distinct for each LMS leaf (or equivalently, for

each  $q$  value). For the Winternitz chaining function, the value of  $u16str(i) || u8str(j)$  is distinct for each invocation of  $H$  for a given leaf. For  $D\_PBLC$  and  $D\_MMSG$ , the input format is used only once for each value of  $q$ , and thus distinctness is assured. The formats for  $D\_INTR$  and  $D\_LEAF$  are used exactly once for each value of  $r$ , which ensures their distinctness. For the recommended pseudorandom key generation process, for a given value of  $I$ ,  $q$  and  $j$  are distinct for each invocation of  $H$ .

The value of  $I$  is chosen uniformly at random from the set of all 128 bit strings. If  $2^{64}$  public keys are generated (and hence  $2^{64}$  random  $I$  values), there is a nontrivial probability of a duplicate (which would imply duplicate prefixes). However, there will be an extremely high probability there will not be a four-way collision (that is, any  $I$  value used for four distinct LMS keys; probability  $< 2^{-132}$ ), and hence the number of repeats for any specific prefix will be limited to at most 3. This is shown (in [Fluhrer17]) to have only a limited effect on the security of the system.

## 9.2. Stateful signature algorithm

The LMS signature system, like all  $N$ -time signature systems, requires that the signer maintain state across different invocations of the signing algorithm, to ensure that none of the component one-time signature systems are used more than once. This section calls out some important practical considerations around this statefulness. These issues are discussed in greater detail in [STMGMT].

In a typical computing environment, a private key will be stored in non-volatile media such as on a hard drive. Before it is used to sign a message, it will be read into an application's Random Access Memory (RAM). After a signature is generated, the value of the private key will need to be updated by writing the new value of the private key into non-volatile storage. It is essential for security that the application ensure that this value is actually written into that storage, yet there may be one or more memory caches between it and the application. Memory caching is commonly done in the file system, and in a physical memory unit on the hard disk that is dedicated to that purpose. To ensure that the updated value is written to physical media, the application may need to take several special steps. In a POSIX environment, for instance, the  $O\_SYNC$  flag (for the  $open()$  system call) will cause invocations of the  $write()$  system call to block the calling process until the data has been written to the underlying hardware. However, if that hardware has its own memory cache, it must be separately dealt with using an operating system or device specific tool such as  $hdparm$  to flush the on-drive cache, or turn off write caching for that drive. Because these details vary across different operating systems and devices,

this note does not attempt to provide complete guidance; instead, we call the implementer's attention to these issues.

When hierarchical signatures are used, an easy way to minimize the private key synchronization issues is to have the private key for the second level resident in RAM only, and never write that value into non-volatile memory. A new second level public/private key pair will be generated whenever the application (re)starts; thus, failures such as a power outage or application crash are automatically accommodated. Implementations SHOULD use this approach wherever possible.

### 9.3. Security of LM-OTS Checksum

To show the security of LM-OTS checksum, we consider the signature  $y$  of a message with a private key  $x$  and let  $h = H(\text{message})$  and  $c = \text{Cksm}(H(\text{message}))$  (see Section 4.5). To attempt a forgery, an attacker may try to change the values of  $h$  and  $c$ . Let  $h'$  and  $c'$  denote the values used in the forgery attempt. If for some integer  $j$  in the range 0 to  $u$ , where  $u = \text{ceil}(8*n/w)$  is the size of the range that the checksum value can cover, inclusive,

$$a' = \text{coef}(h', j, w),$$

$$a = \text{coef}(h, j, w), \text{ and}$$

$$a' > a$$

then the attacker can compute  $F^{a'}(x[j])$  from  $F^a(x[j]) = y[j]$  by iteratively applying function  $F$  to the  $j$ -th term of the signature an additional  $(a' - a)$  times. However, as a result of the increased number of hashing iterations, the checksum value  $c'$  will decrease from its original value of  $c$ . Thus a valid signature's checksum will have, for some number  $k$  in the range  $u$  to  $(p-1)$ , inclusive,

$$b' = \text{coef}(c', k, w),$$

$$b = \text{coef}(c, k, w), \text{ and}$$

$$b' < b$$

Due to the one-way property of  $F$ , the attacker cannot easily compute  $F^{b'}(x[k])$  from  $F^b(x[k]) = y[k]$ .

## 10. Comparison with other work

The eXtended Merkle Signature Scheme (XMSS) [XMSS], [RFC8391] is similar to HSS in several ways. Both are stateful hash based signature schemes, and both use a hierarchical approach, with a Merkle tree at each level of the hierarchy. XMSS signatures are slightly shorter than HSS signatures, for equivalent security and an equal number of signatures.

HSS has several advantages over XMSS. HSS operations are roughly four times faster than the comparable XMSS ones, when SHA256 is used as the underlying hash. This occurs because the hash operation done as a part of the Winternitz iterations dominates performance, and XMSS performs four compression function invocations (two for the PRF, two for the F function) where HSS needs only perform one. Additionally, HSS is somewhat simpler (as each hash invocation is just a prefix followed by the data being hashed).

## 11. Acknowledgements

Thanks are due to Chirag Shroff, Andreas Huelsing, Burt Kaliski, Eric Osterweil, Ahmed Kosba, Russ Housley, Philip Lafrance, Alexander Truskovsky, Mark Peruzel for constructive suggestions and valuable detailed review. We especially acknowledge Jerry Solinas, Laurie Law, and Kevin Igoe, who pointed out the security benefits of the approach of Leighton and Micali [USPTO5432852] and Jonathan Katz, who gave us security guidance, and Bruno Couillard and Jim Goodman for an especially thorough review.

#### Appendix A. Pseudorandom Key Generation

An implementation MAY use the following pseudorandom process for generating an LMS private key.

SEED is an m-byte value that is generated uniformly at random at the start of the process,

I is LMS key pair identifier,

q denotes the LMS leaf number of an LM-OTS private key,

x<sub>q</sub> denotes the x array of private elements in the LM-OTS private key with leaf number q,

i is the index of the private key element, and

H is the hash function used in LM-OTS.

The elements of the LM-OTS private keys are computed as:

$$x_{q}[i] = H(I \parallel u32str(q) \parallel u16str(i) \parallel u8str(0xff) \parallel SEED).$$

This process stretches the m-byte random value SEED into a (much larger) set of pseudorandom values, using a unique counter in each invocation of H. The format of the inputs to H are chosen so that they are distinct from all other uses of H in LMS and LM-OTS. A careful reader will note that this is similar to the hash we perform

when iterating through the Winternitz chain; however in that chain, the iteration index will vary between 0 and 254 maximum (for  $W=8$ ), while the corresponding value in this formula is 255. This algorithm is included in the proof of security in [Fluhrer17] and hence this method is safe when used within the LMS system; however any other cryptographical secure method of generating private keys would also be safe.

#### Appendix B. LM-OTS Parameter Options

The LM-OTS one time signature method uses several internal parameters, which are a function of the selected parameter set. These internal parameters set:

$p$  - This is the number of independent Winternitz chains used in the signature; it will be the number of  $w$ -bit digits needed to hold the  $n$ -bit hash ( $u$  in the below equations), along with the number of digits needed to hold the checksum ( $v$  in the below equations)

$ls$  - This is the size of the shift needed to move the checksum so that it appears in the checksum digits

$ls$  is needed because, while we express the checksum internally as a 16 bit value, we don't always express all 16 bits in the signature; for example, if  $w=4$ , we might use only the top 12 bits. Because we read the checksum in network order, this means that, without the shift, we'll use the higher order bits (which may be always 0), and omit the lower order bits (where the checksum value actually resides). This shift is here to ensure that the parts of the checksum we need to express (for security) actually contribute to the signature; when multiple such shifts are possible, we take the minimal value.

The parameters  $ls$ , and  $p$  are computed as follows:

```

u = ceil(8*n/w)
v = ceil((floor(lg((2^w - 1) * u)) + 1) / w)
ls = 16 - (v * w)
p = u + v

```

Here  $u$  and  $v$  represent the number of  $w$ -bit fields required to contain the hash of the message and the checksum byte strings, respectively. And as the value of  $p$  is the number of  $w$ -bit elements of  $(H(\text{message}) \parallel \text{Cksm}(H(\text{message})))$ , it is also equivalently the number of byte strings that form the private key and the number of byte strings in the signature. The value 16 in the  $ls$  computation of  $ls$  corresponds to the 16 bits value used for the sum variable in Algorithm 2 in Section 4.4

A table illustrating various combinations of  $n$  and  $w$  with the associated values of  $u$ ,  $v$ ,  $ls$ , and  $p$  is provided in Table 6.

| Hash Length in Bytes ( $n$ ) | Winternitz Parameter ( $w$ ) | $w$ -bit Elements in Hash ( $u$ ) | $w$ -bit Elements in Checksum ( $v$ ) | Left Shift ( $ls$ ) | Total Number of $w$ -bit Elements ( $p$ ) |
|------------------------------|------------------------------|-----------------------------------|---------------------------------------|---------------------|-------------------------------------------|
| 32                           | 1                            | 256                               | 9                                     | 7                   | 265                                       |
| 32                           | 2                            | 128                               | 5                                     | 6                   | 133                                       |
| 32                           | 4                            | 64                                | 3                                     | 4                   | 67                                        |
| 32                           | 8                            | 32                                | 2                                     | 0                   | 34                                        |

Table 6

#### Appendix C. An iterative algorithm for computing an LMS public key

The LMS public key can be computed using the following algorithm or any equivalent method. The algorithm uses a stack of hashes for data. It also makes use of a hash function with the typical `init/update/final` interface to hash functions; the result of the invocations `hash_init()`, `hash_update(N[1])`, `hash_update(N[2])`, ..., `hash_update(N[n])`, `v = hash_final()`, in that order, is identical to that of the invocation of `H(N[1] || N[2] || ... || N[n])`.

## Generating an LMS Public Key from an LMS Private Key

```

for ( i = 0; i < 2^h; i = i + 1 ) {
  r = i + num_lmots_keys;
  temp = H(I || u32str(r) || u16str(D_LEAF) || OTS_PUB_HASH[i])
  j = i;
  while (j % 2 == 1) {
    r = (r - 1)/2;
    j = (j-1) / 2;
    left_side = pop(data stack);
    temp = H(I || u32str(r) || u16str(D_INTR) || left_side || temp)
  }
  push temp onto the data stack
}
public_key = pop(data stack)

```

Note that this pseudocode expects that all  $2^h$  leaves of the tree have equal depth; that is, `num_lmots_keys` to be a power of 2. The maximum depth of the stack will be  $h-1$  elements, that is, a total of  $(h-1)*n$  bytes; for the currently defined parameter sets, this will never be more than 768 bytes of data.

## Appendix D. Method for deriving authentication path for a signature

The LMS signature consists of `u32str(q) || lmots_signature || u32str(type) || path[0] || path[1] || ... || path[h-1]`. This appendix shows one method of constructing this signature, assuming that the implementation has stored the `T[]` array that was used to construct the public key. Note that this is not the only possible method; other methods exist which don't assume that you have the entire `T[]` array in memory. To construct a signature, you perform the following algorithm:

## Generating an LMS Signature

1. set type to the typecode of the LMS algorithm
2. extract h from the typecode according to table 2
3. create the LM-OTS signature for the message:  
`ots_signature = lmots_sign(message, LMS_PRIV[q])`
4. compute the array path as follows:
 

```

i = 0
r = 2^h + q
while (i < h) {
    temp = (r / 2^i) xor 1
    path[i] = T[temp]
    i = i + 1
}

```
5. `S = u32str(q) || ots_signature || u32str(type) || path[0] || path[1] || ... || path[h-1]`
6. `q = q + 1`
7. return S

where 'xor' is the bitwise exclusive-or operation, and / is integer division (that is, rounded down to an integer value)

## Appendix E. Example Implementation

An example implementation can be found online at <https://github.com/cisco/hash-sigs>.

## Appendix F. Test Cases

This section provides test cases that can be used to verify or debug an implementation. This data is formatted with the name of the elements on the left, and the value of the elements on the right, in hexadecimal. The concatenation of all of the values within a public key or signature produces that public key or signature, and values that do not fit within a single line are listed across successive lines.

## Test Case 1 Public Key

The ACPKM internal re-keying mechanism for block cipher modes of  
operation  
draft-smyshlyaev-re-keying-00

#### Abstract

This specification presents an approach to increase the security of block cipher operation modes based on re-keying (with no additional keys needed) during each separate message processing. It provides an internal re-keying mechanism called ACPKM. This mechanism doesn't require additional secret parameters or complicated transforms - for key update only the base encryption function is used.

#### Status of This Memo

This Internet-Draft is submitted in full conformance with the provisions of BCP 78 and BCP 79.

Internet-Drafts are working documents of the Internet Engineering Task Force (IETF). Note that other groups may also distribute working documents as Internet-Drafts. The list of current Internet-Drafts is at <http://datatracker.ietf.org/drafts/current/>.

Internet-Drafts are draft documents valid for a maximum of six months and may be updated, replaced, or obsoleted by other documents at any time. It is inappropriate to use Internet-Drafts as reference material or to cite them other than as "work in progress."

This Internet-Draft will expire on April 24, 2017.

## 1. Introduction

An important problem related to secure functioning of any cryptographic system is the control of key lifetimes. Regarding symmetric keys, the main concern is constraining the key exposure. It could be done by limiting the maximal amount of data processed with one key. The restrictions can come either from combinatorial properties of the used cipher modes of operation (for example, birthday attack [BDJR]) or from particular cryptographic attacks on the used block cipher (for example, linear cryptanalysis [Matsui]). Moreover, most strict restrictions here follow from the need to resist side-channel attacks. The adversary's opportunity to obtain an essential amount of data processed with a single key leads not only to theoretic but also to real vulnerabilities (see [BL]). Therefore, when the total size of a plaintext processed with the same key reaches threshold values, this key cannot be used anymore and certain procedures on encryption keys are needed. It leads to several operating limitations, e.g. the impossibility to process long messages and processing overhead caused by derivation of additional keys.

This specification presents a mechanism to increase the key lifetime, which is called ACPKM. This solution ("key meshing") transforms the key value each time when the given amount of data, precisely the amount of plaintext section (not the total amount of separate messages), is processed and proceeds with a new transformed key value for a new plaintext section. Such a transformation does not require any additional secret values. It is integrated into the base mode of operation and can be considered as it's extension, therefore it is called "internal re-keying" in this document.

This approach seems to be mostly useful in the case when the total amount of data for an established key is not known beforehand: the performance on useless operations won't be lost if the data size is rather small, and the security won't be lacked when it occurs to be large. The transformed keys are computed only when they are needed.

## 2. Conventions Used in This Document

The key words "MUST", "MUST NOT", "REQUIRED", "SHALL", "SHALL NOT", "SHOULD", "SHOULD NOT", "RECOMMENDED", "MAY", and "OPTIONAL" in this document are to be interpreted as described in [RFC2119].

## 3. Basic Terms and Definitions

This document uses the following terms and definitions for the sets and operations on the elements of these sets:

- (xor) exclusive-or of two binary vectors of the same length.
- $V^*$  the set of all strings of a finite length (hereinafter referred to as strings), including the empty string;
- $V_s$  the set of all binary strings of length  $s$ , where  $s$  is a non-negative integer; substrings and string components are enumerated from right to left starting from one;
- $|X|$  the bit length of the bit string  $X$ ;
- $A|B$  concatenation of strings  $A$  and  $B$  both belonging to  $V^*$ , i.e., a string in  $V_{|A|+|B|}$ , where the left substring in  $V_{|A|}$  is equal to  $A$ , and the right substring in  $V_{|B|}$  is equal to  $B$ ;
- $Z_{2^n}$  ring of residues modulo  $2^n$ ;
- $Int_s: V_s \rightarrow Z_{2^s}$  the transformation that maps a string  $a = (a_s, \dots, a_1)$ ,  $a$  in  $V_s$ , into the integer  $Int_s(a) = 2^s a_s + \dots + 2 a_2 + a_1$ ;

$\text{Vec}_s: \mathbb{Z}_{\{2^s\}} \rightarrow V_s$  the transformation inverse to the mapping  
 $\text{Int}_s$ ;  
 $\text{MSB}_i: V_s \rightarrow V_i$  the transformation that maps the string  $a = (a_s, \dots, a_1)$  in  $V_s$ , into the string  $\text{MSB}_i(a) = (a_s, \dots, a_{s-i+1})$  in  $V_i$ ;  
 $\text{LSB}_i: V_s \rightarrow V_i$  the transformation that maps the string  $a = (a_s, \dots, a_1)$  in  $V_s$ , into the string  $\text{LSB}_i(a) = (a_i, \dots, a_1)$  in  $V_i$ ;  
 $\text{Inc}_c: V_s \rightarrow V_s$  the transformation that maps the string  $a = (a_s, \dots, a_1)$  in  $V_s$ , into the string  $\text{Inc}_c(a) = \text{MSB}_{\{|a|-c\}}(a) \mid \text{Vec}_c(\text{Int}_c(\text{LSB}_c(a)) + 1 \pmod{2^c})$  in  $V_s$ ;  
 $0^s$  denotes the string  $a$  in  $V_s$  that consists of  $s$  '0' bits;  
 $E_K: V_n \rightarrow V_n$  the block cipher permutation under the key  $K$  in  $V_k$ ;  
 $k$  the key  $K$  size (in bits);  
 $n$  the block size of the block cipher (in bits);  
 $b$  the total number of data blocks in the plaintext;  
 $N$  the section size (the number of bits in a data section);  
 $l$  the number of data sections in the plaintext;  
 $m$  the message  $M$  size (in bits);  
 $\text{phi}_i: V_s \rightarrow V_s$  the transformation that maps a string  $a = (a_s, \dots, a_1)$  into the string  $\text{phi}_i(a) = a' = (a'_s, \dots, a'_1)$ ,  $1 \leq i \leq s$ , such that  $a'_i = 1$  and  $a'_j = a_j$  for all  $j$  in  $\{1, \dots, s\} \setminus \{i\}$ ;  
 $\text{ceil}(x)$  the least integer that is not less than  $x$ .

#### 4. CTR and GCM Block Cipher Modes

This section describes the families of block cipher modes of operations that are extended by the ACPKM re-keying mechanisms as described in Section 5.

A plaintext message  $P$  and a ciphertext  $C$  are divided into  $b = \text{ceil}(m/n)$  parts (denoted as  $P = P_1 \mid P_2 \mid \dots \mid P_b$  and  $C = C_1 \mid C_2 \mid \dots \mid C_b$ , where  $P_i$  and  $C_i$  are in  $V_n$ , for  $i = 1, 2, \dots, b-1$ , and  $P_b, C_b$  are in  $V_r$ , where  $r \leq n$ ).

#### 4.1. CTR Block Cipher Mode

The Counter (CTR) mode is a block cipher mode of operation that applies the block cipher transformation  $E_K$  to a sequence of input blocks, called counters, to produce a sequence of output blocks that are XORed with a plaintext to produce a ciphertext, and vice versa. It is defined similar to the one specified in [NIST-CTR].

The ACPKM-CTR re-keying mechanisms described in Section 5.1 can be used with the following block cipher and CTR mode parameters:

- o  $64 \leq n \leq 512$ ;
- o  $128 \leq k \leq 512$ ;
- o the number of bits  $c$  in a specific part of the block to be incremented is such that  $32 \leq c \leq 3/4 n$ .

In the current document, the counters for a given message are denoted as  $CTR_1, CTR_2, \dots, CTR_b$ .

The CTR encryption mode is defined as follows:

Input:

Initial counter nonce ICN in  $V_{\{n-c\}}$ ,  
plaintext  $P$ ,  $|P| < n \cdot 2^c$ .

Output:

Ciphertext  $C$ .

---

CTR Encryption:

1.  $CTR_1 = ICN \parallel 0^c$ .
2. For  $j = 1, 2, \dots, b-1$  do  
     $CTR_{\{j+1\}} = Inc_c(CTR_j)$ .
3. For  $j = 1, 2, \dots, b$  do  
     $G_j = E_K(CTR_j)$ .
4.  $C = P \text{ (xor) } MSB_{\{|P|\}}(G_1 \parallel \dots \parallel G_b)$ .
5. Return  $C$ .

The CTR decryption mode is defined as follows:

## Input:

Initial counter nonce ICN in  $V_{\{n-c\}}$ ,  
ciphertext  $C$ ,  $|C| < n \cdot 2^c$ .

## Output:

Plaintext  $P$ .

---

CTR Decryption:

1.  $CTR_1 = ICN \parallel 0^c$ .
2. For  $j = 1, 2, \dots, b-1$  do  
     $CTR_{\{j+1\}} = Inc_c(CTR_j)$ .
3. For  $j = 1, 2, \dots, b$  do  
     $G_j = E_K(CTR_j)$
4.  $P = C \text{ (xor) } MSB_{\{|C|\}}(G_1 \parallel \dots \parallel G_b)$ .
5. Return  $P$ .

The initial counter nonce ICN value for each message that is encrypted under the given key must be chosen in a unique manner.

#### 4.2. GCM Block Cipher Mode

TODO: This section describes the family of block cipher modes of operation with both encryption and authentication. It is defined similar to the one specified in [NIST-GCM].

The ACPKM-GCM re-keying mechanisms described in Section 5.2 can be used with the following GCM block cipher mode parameters:

- o  $128 \leq n \leq 512$ ;
- o  $128 \leq k \leq 512$ ;
- o the number of bits  $c$  in a specific part of the block to be incremented is such that  $32 \leq c \leq 3/4 n$ .

##### 4.2.1. GCM Subprocedures

This section presents three mathematical algorithms that appear in the specification of the authenticated encryption and authenticated decryption functions of the GCM cipher mode described in Section 4.2.2 below.

###### 4.2.1.1. Multiplication Operation on Blocks

The  $*$  operation on (pairs of) the  $2^n$  possible blocks corresponds to the multiplication operation for the binary Galois (finite) field of  $2^n$  elements and is defined by a particular GCM mode.

## 4.2.1.2. GHASH Function

Algorithm 2: GHASH\_H(X)

=====

Input:

Bit string  $X = X_1 \mid \dots \mid X_m$ , where  $X_i$  in  $V_n$  for  $i$  in  $1, \dots, m$ .

Output:

Block GHASHH (X) in  $V_n$ 

- 
1.  $Y_0 = 0^n$ .
  2. For  $i = 1, \dots, m$  do
    - $Y_i = (Y_{i-1} \text{ (xor) } X_i) * H$ .
  3. Return  $Y_m$ .

## 4.2.1.3. GCTR Function

Algorithm 3: GCTR\_K(ICB, X)

=====

Input:

Initial counter block ICB;

 $X = X_1 \mid \dots \mid X_t$ ,  $X_i$  in  $V_n$  for  $i = 1, \dots, t-1$  and  $X_t$  in  $V_r$ ,  
where  $r \leq n$ .

Output:

 $Y$  in  $V_{\{|X|\}}$ .

- 
1. If  $X$  in  $V_0$  then return  $Y$ , where  $Y$  in  $V_0$ .
  2.  $t = \text{ceil}(|X|/n)$ .
  3.  $GCTR_1 = ICB$ .
  4. For  $i = 2, \dots, t$  do
    - $GCTR_i = \text{Inc}_c(GCTR_{i-1})$ .
  5. For  $i = 1, \dots, t$  do
    - $G_i = E_K(GCTR_i)$ .
  6.  $Y = X \text{ (xor) } \text{MSB}_{\{|X|\}}(G_1 \mid \dots \mid G_t)$ .
  7. Return  $Y$ .

## 4.2.2. GCM Mode Description

The GCM encryption mode is defined as follows:

## Input:

Initialization vector IV in  $V_{\{n-c\}}$ ,  
 plaintext P,  $|P| < n \cdot (2^c - 2)$ .  
 additional authenticated data A.

## Output:

Ciphertext C,  
 authentication tag T.

---

GCM Encryption:

1.  $H = E_K(0^n)$ .
2. if  $c = 32$ , then  $J_0 = IV \parallel 0^{31} \parallel 1$ ;  
 if  $c \neq 32$ , then  $s = n \cdot \text{ceil}(|IV|/n) - |IV|$ ,  
 $J_0 = \text{GHASH}_H(IV \parallel 0^{\{s+n-64\}} \parallel \text{Vec}_{64}(|IV|))$ .
3.  $C = \text{GCTR}_K(\text{Inc}_{32}(J_0), P)$ .
4.  $u = n \cdot \text{ceil}(|C|/n) - |C|$ ,  
 $v = n \cdot \text{ceil}(|A|/n) - |A|$ .
5.  $S = \text{GHASH}_H(A \parallel 0^v \parallel C \parallel 0^u \parallel 0^{\{n-128\}} \parallel$   
 $\text{Vec}_{64}(|A|) \parallel \text{Vec}_{64}(|C|))$ .
6.  $T = \text{MSB}_t(E_K(J_0) \text{ (xor) } S)$ .
7. Return  $C \parallel T$ .

The GCM decryption mode is defined as follows:

## Input:

Initialization vector IV in  $V_{\{n-c\}}$ ,  
 ciphertext C,  $|C| < n \cdot (2^c - 2)$ ,  
 authentication tag T,  
 additional authenticated data A.

## Output:

Plaintext P or FAIL.

---

GCM decryption:

1.  $H = E_K(0^n)$ .
2. if  $c = 32$ , then  $J_0 = IV \parallel 0^{31} \parallel 1$ ;  
 if  $c \neq 32$ , then  $s = n \cdot \text{ceil}(|IV|/n) - |IV|$ ,  
 $J_0 = \text{GHASH}_H(IV \parallel 0^{\{s+n-64\}} \parallel \text{Vec}_{64}(|IV|))$ .
3.  $P = \text{GCTR}_K(\text{Inc}_{32}(J_0), C)$ .
4.  $u = n \cdot \text{ceil}(|C|/n) - |C|$ ,  
 $v = n \cdot \text{ceil}(|A|/n) - |A|$ .
5.  $S = \text{GHASH}_H(A \parallel 0^v \parallel C \parallel 0^u \parallel 0^{\{n-128\}} \parallel$   
 $\text{Vec}_{64}(|A|) \parallel \text{Vec}_{64}(|C|))$ .
6.  $T' = \text{MSB}_t(E_K(J_0) \text{ (xor) } S)$ .
7. IF  $T=T'$  then return P; else return FAIL.

The initial vector IV value for each message that is encrypted under the given key must be chosen in a unique manner.

Note : The encryption part in the GCM-ACPKM mode is the encryption in the CTR-ACPKM mode with several differences: in the CTR mode the counter for the plaintext encryption starts with the first CTR\_1 value and in the GCM mode the counter starts with the second GCTR\_2 value.

5. ACPKM re-keying mechanisms

This section defines periodical key transformations for long message processing that are considered as extensions of the basic CTR and GCM encryption modes and are called ACPKM-CTR and ACPKM-GCM re-keying mechanisms.

An additional parameter that defines the functioning of CTR and GCM block cipher modes with the ACPKM key transformation algorithm is the section size N. The value of N is fixed within a specific protocol based on the requirements of the system capacity and key lifetime (some recommendations on choosing N will be provided in Section 7). The section size N MUST be divisible by the block size n.

The main idea behind internal re-keying is presented in Fig.1:

Lifetime of a key = L,  
 section size = const = N,  
 maximum message size = m\_max.

$l\_max = \text{ceil}(m\_max/N),$   
 $q*N \leq L.$

Figure 1: Key meshing approach

For the {i+1}-th section the  $K_{\{i+1\}}$  value is calculated as follows:

$$K_{\{i+1\}} = \text{ACPKM-CTR}(K_i) = \text{MSB}_k(E_{\{K_i\}}(W_1) \mid \dots \mid E_{\{K_i\}}(W_J)),$$

where  $J = \text{ceil}(k/n), W_t = \text{phi}_c(D_t)$  for any t in  $\{1, \dots, J\}$  and  $D_1, D_2, \dots, D_J$  are in  $V_n$  and are calculated as follows:

$D_{-1} \mid D_{-2} \mid \dots \mid D_{-J} = \text{MSB}_{\{J*n\}}(D),$

where  $D$  is the following constant in  $V_{1024}$ :

|       |    |    |    |    |    |    |    |      |
|-------|----|----|----|----|----|----|----|------|
| D = ( | F3 | 74 | E9 | 23 | FE | AA | D6 | DD   |
|       | 98 | B4 | B6 | 3D | 57 | 8B | 35 | AC   |
|       | A9 | 0F | D7 | 31 | E4 | 1D | 64 | 5E   |
|       | 40 | 8C | 87 | 87 | 28 | CC | 76 | 90   |
|       | 37 | 76 | 49 | 9F | 7D | F3 | 3B | 06   |
|       | 92 | 21 | 7B | 06 | 37 | BA | 9F | B4   |
|       | F2 | 71 | 90 | 3F | 3C | F6 | FD | 1D   |
|       | 70 | BB | BB | 88 | E7 | F4 | 1B | 76   |
|       | 7E | 44 | F9 | 0E | 46 | 91 | 5B | 57   |
|       | 00 | BC | 13 | 45 | BE | 0D | BD | C7   |
|       | 61 | 38 | 19 | 3C | 41 | 30 | 86 | 82   |
|       | 1A | A0 | 45 | 79 | 23 | 4C | 4C | F3   |
|       | 64 | F2 | 6A | CC | EA | 48 | CB | B4   |
|       | 0C | B9 | A9 | 28 | C3 | B9 | 65 | CD   |
|       | 9A | CA | 60 | FB | 9C | A4 | 62 | C7   |
|       | 22 | C0 | 6C | E2 | 4A | C7 | FB | 5B). |

**Note** : The constant  $D$  is such that  $\text{phi}_c(D_{-1}), \dots, \text{phi}_c(D_{-J})$  are pairwise different for any allowed  $n, k, c$  values.

#### 5.1. ACPKM internal re-keying mechanism for CTR encryption mode

This section defines a ACPKM-CTR internal re-keying mechanism for the CTR encryption mode that was described in Section 4.1.

During the processing of the input message  $M$  with the length  $m$  using ACPKM-CTR internal re-keying algorithm and the key  $K$  the message is divided into  $l = \text{ceil}(m*N)$  parts (denoted as  $M = M_{-1} \mid M_{-2} \mid \dots \mid M_{-l}$ , where  $M_{-i}$  is in  $V_N$  for  $i = 1, 2, \dots, l-1$  and  $M_{-l}$  is in  $V_r, r \leq N$ ). The first section is processed with the initial key  $K_{-1} = K$ . To process the  $(i+1)$ -th section the  $K_{\{i+1\}}$  key value is calculated using ACPKM-CTR transformation of the key  $K_{-i}$ . The counter value ( $\text{CTR}_{\{i+1\}}$ ) is not changed during this process.

The message size  $m$  MUST NOT exceed  $n*2^{\{c-1\}}$  bits.

#### 5.2. ACPKM internal re-keying mechanism for GCM encryption mode

This section defines a ACPKM-GCM internal re-keying mechanism for the GCM encryption mode that was described in Section 4.2.

During the processing of the input message  $M$  with the length  $m$  using ACPKM-GCM internal re-keying algorithm and the key  $K$  the message is divided into  $l = \text{ceil}(m/N)$  parts (denoted as  $M = M_{-1} \mid M_{-2} \mid \dots \mid M_{-l}$ ,

where  $M_i$  is in  $V_N$  for  $i = 1, 2, \dots, l-1$  and  $M_l$  is in  $V_r$ ,  $r \leq N$ ). The first section is processed with the initial key  $K_1 = K$ . To process the  $(i+1)$ -th section the  $K_{i+1}$  key value is calculated using ACPKM-GCM transformation of the key  $K_i$ .

The message size  $m$  MUST NOT exceed  $n \cdot (2^{c-1} - 2)$  bits.

The key for computing values  $E_K(J_0)$  and  $H$  is not updated and is equal to the initial key.

## 6. Acknowledgments

TODO

## 7. Security Considerations

The ACPKM re-keying mechanisms provide the CTR and GCM encryption modes extensions that have the following property: a compromise of a key of some section does not lead to a compromise of previous keys but leads to a compromise of next keys.

The ACPKM mechanism allows to increase the CTR and GCM encryption modes security in proportion to the frequency of key changing, which is inversely related to the section size  $N$ . Thus, the key lifetime can be noticeably increased: an amount of material that is processed with the key  $K$  increases quadratically, divided by  $N$ .

Since the performance of encryption can slightly decrease for rather small values of  $N$ , the parameter of  $N$  SHOULD be selected for a particular protocol as maximum possible to provide necessary key lifetime for the adversary models that are considered.
